INFECTION AND RESISTANCE

CHAPTER 42

TYPES OF IMMUNITY

THE term *immunity*, used as we use it here, needs definition. As plain English, it does not mean what it says. This does not matter very much because, as Whitehead points out so aptly in his *Introduction to Mathematics*, the scientist shares with Humpty Dumpty the privilege of paying words extra and making them mean what he likes. But if we are to avoid confusion we must at least give our words definite orders and see that they are obeyed. It happens that the state suggested by the word that we have chosen as a generic label for the phenomena we wish to study is one about which we know very little, except that it exists. We have indeed not bothered very much about it. Complete natural insusceptibility to infection removes the relationship between the particular host and parasite concerned from our field of interest, except in so far as we can learn from any instance of this kind something of the genetic laws that determine the transmission of this innate and complete resistance. Our main business is with those interactions between parasite and host that are characterized by a fluctuating equilibrium, and with the factors that shift this equilibrium, so that sometimes the parasite, sometimes the host, gains the upper hand. *Resistance* would be a better word than *Immunity*; but *Immunity* will serve well enough so long as we make it quite clear that we are using it to denote the resultant of two opposing systems, and that this resultant can assume any value from zero to infinity.

And our name misleads a little because of its associations. It happens to have been frequently applied to the data obtained by a particular kind of technique, and there has been a tendency to confuse technique with subject-matter. The special methods devised by the immunologist—if he must accept the unpleasing name that custom has given him—are applicable to problems with which he has no concern; while the field proper to his study extends far beyond the limits that would be imposed by any definition in terms of the particular technique employed. The student of immunity is concerned with all data relating to the mechanisms involved in infective disease, by whatever means they are obtained. Any account given at the present time must stress unduly a particular set of phenomena, simply because they are the only phenomena that have as yet been adequately studied; but this is a historical accident that will be remedied by time.

The phenomena that present themselves for study are derived from the most

diverse sources. Some come to us from epidemiology, using that term in its widest sense. Under natural conditions different animal species show a widely differing incidence of certain infections. Thus, anthrax is in the main a disease of herbivora. Of the animals dying of anthrax in this country in 1914, 733 were cattle, 5 were sheep, 32 were swine and 25 were horses. In Australia and South America sheep are more commonly affected; but Algerian sheep are stated to be highly resistant. Tuberculosis is one of the commonest natural infections of man and cattle. It is common in pigs and in fowls. It is relatively uncommon in sheep, goats, horses and dogs. It is stated to be very uncommon as a natural disease in rabbits, guinea-pigs, rats and mice. Among mankind there are well-marked racial differences in its incidence and severity. In eight of the great cities of the United States in 1920 the mortality from tuberculosis among the white population varied from 0·794 to 1·216 per 1,000 living; among the coloured population it varied from 2·855 to 4·205 per 1,000. Such instances could be multiplied *ad nauseam*.

The epidemiologist also records differences in the incidence and fatality of various infective diseases at different ages, suggesting in many cases an increase in resistance with age. He notes also that repeated attacks of the same infective diseases are in some instances very rare, as in measles, or smallpox, or diphtheria, or typhoid fever, while in others they are relatively common, as in influenza, or pneumonia, or the common cold.

Other data come to us from clinical medicine in the narrower sense. Infections that, in their usual course, progress slowly to death or recovery sometimes assume a fulminating form. Such a protean infection as tuberculosis shows the widest diversity in the varying prominence of its local and general manifestations. And, in any infective disease, why do some patients die and others recover?

For the immunologist these are crude data that require analysis. Using his own methods he re-examines the phenomena presented by natural infection. Sometimes he transforms the picture they present. He finds, for instance, that the recorded frequency of natural tuberculosis in various animal species does not in all cases reflect their relative resistance to experimental infection (see Chapter 59). He discovers also that there may be a diversity of immunological states within a single clinical syndrome. This is true of tuberculosis; there are different types of the tubercle bacillus, and a given host species is more resistant to one type than to another. It is true of lobar pneumonia. For the immunologist this is not one disease but several, each caused by a significantly different type of pneumococcus; and he notes that the statement that second attacks of pneumonia are not uncommon may belong to the Baconian category of a truth that has in it a mixture of a lie. Again he finds that enteric fever is not one but many; and his attempts at interference are planned accordingly.

Another important change that the immunologist makes in the clinical and epidemiological picture is in regard to the character and extent of the association between any given parasite and the host species that it infects. He finds that the real range of interaction includes states of equilibrium in which the host shows no overt signs of disease. Whether we call all these conditions latent infections, or refer to many of the hosts as healthy carriers, matters little. No hair-splitting definition will help us much. The significant thing we have learned is that in some infections, such as measles, contact between a previously uninfected host and the virus of the disease usually results in a clinically characteristic attack, so that the epidemiological picture gives us a reasonably adequate description of

the biological association, while in other diseases, such as cerebrospinal meningitis or poliomyelitis, the clinically diagnosable cases form so small a fraction of the total number of infected persons that they might almost be regarded as occasional accidents in an association that, in its modal form, induces no such serious effects.

In re-examining the data that he receives from the field and from the ward, the immunologist relies in large part on experiments on animals. When he tries to interpret his data he is forced to rely almost entirely on this fundamental method of study. He cannot advance without some simplification of his problems, some control, at least, over the innumerable variables that determine the incidence and results of infective disease as it occurs in nature.

By such experiments he has found that he can increase the resistance of animals by infecting them with sublethal doses of a given pathogenic organism, or by injecting an organism that has lost its power to kill—though here he was forestalled by Jenner's experiment of vaccination in man—or, more safely and conveniently, by injecting dead organisms or their products. From analogy, and from the fact that he can demonstrate similar changes in the tissue fluids, he concludes that this artificial immunization in animals is essentially similar to the natural immunization that occurs during an attack of an infective disease. Since the tissues of the naturally infected or artificially immunized host play an active part in bringing about this increased resistance, he calls it *active immunity*. In some cases he finds that he can transmit this resistant state to a normally susceptible animal by injecting into it the serum of another animal that has been rendered immune. Since the tissues of the recipient appear to play a relatively passive part, he calls this *passive immunity*. He also finds that immunity of this kind is sometimes transmitted naturally from a mother to her young, either by the passage of the protective substances *via* the placental vessels, or by their ingestion during the first days or weeks of life in the colostrum. This he calls *congenital passive immunity*.

And so, if he has a taste for classification, the immunologist can draw up some such list as this:

1. Innate Immunity.

2. Acquired Immunity.
   - (*a*) Active.
     - (α) Naturally acquired.
     - (β) Artificially induced.
   - (*b*) Passive.
     - (α) Naturally acquired (congenital).
     - (β) Artificially induced.

Innate, or Genetic, Immunity.

Of innate as opposed to acquired immunity, little need here be said. We have noted that different animal species may display wide differences in their resistance to various bacterial parasites, or to their toxins. This species immunity is of great practical importance in relation to the communicability of infective disease from animals to man, or from one animal species to another.

There can be no doubt that differences in innate resistance also occur within any animal species, one individual differing from another in this biological character as in any other. Of the extent of these differences and of the laws that govern their inheritance we as yet know very little. Within recent years a number of workers have attempted to study this problem by direct experiment, and their results indicate that it is possible to increase or lower the average resistance of a given strain of rats, mice or other experimental animals, by selective breeding. (See for instance Webster 1923, 1924*a*, *b*, 1925, 1933*a*, *b*, Pritchett 1925, 1926*a*, *b*, Lambert and Knox 1928, Irwin 1929, 1933, Irwin and Hughes 1931, 1933, Lambert 1932, Schott 1932, Gowen 1933, Gowen and Schott 1933*a*, *b*, *c*, Schütze *et al.* 1936, Hill *et al.*, 1940, Lurie 1941, Gowen and Calhoun 1943).

Experiments of this type are, however, subject to great technical difficulties. The obvious method of obtaining a strain of animals with a high genetic resistance is to infect an adequate sample with the bacterium under study, breed from the survivors, and repeat the process through several subsequent generations. This plan has, in fact, been followed by some of the workers referred to above ; but it is clearly open to serious sources of error. In testing the resistance of our original generation we shall certainly alter it, and the effect of this alteration will not be confined to the parent animals. The surviving females will pass on a temporary passive immunity to their young ; and, since most of the species commonly employed in such tests attain sexual maturity within a few months at most, this congenital passive immunity may persist until the F_1 generation are tested. A much more serious source of error is that the survivors will often be carriers of the organisms with which they were infected. Either the male or female parent may thus infect the young, inducing in them an acquired active immunity, or adding it to the congenital passive immunity already present. If this source of error is avoided, by mating the original sample of animals at random, and testing them after they have been separated from their young, the number of animals that must be employed, and the resulting labour, are enormously increased ; since it will only be by chance that both parents of any one litter will be found to possess a resistance above, or below, the average.

The papers referred to above describe various attempts to overcome, or minimize, these technical difficulties ; and they are very fully discussed in a recent monograph by Hill (1934). His conclusion is that, while possible errors of the kind we have mentioned render doubtful many of the observations that have been recorded, a presumptive case has been established for the existence of genetic differences in resistance within a breed or species, as well as between breeds or between species. In regard to the degree of these genetic differences, within a strain or breed, it is much more difficult to arrive at any just conclusion. Some of the differences recorded have, in fact, been quite trivial ; but a few have been of a relatively high order.

As an example of the latter we may quote results recorded by Webster (1933*b*). By selective breeding, carried out through several generations, he was able to obtain a particularly resistant, and a particularly susceptible strain of mice, both originally derived from the strain that has been bred for many years at the Rockefeller Institute. The organism against which they were tested, in each successive generation, was *Salm. enteritidis*. The susceptible strain finally developed showed a mortality of 85 to 95 per cent. when infected with this organism, while the resistant strain showed a mortality of the order of 15 per cent. It is of interest to note that the difference in resistance between these two strains was non-specific, in the ordinary bacteriological sense. Thus the susceptible strain showed a mortality of 63 per cent., when tested against *Past. septica*, 80 per cent. when tested against Friedländer's bacillus, and 38 per cent. when tested against the pneu-

mococcus, while the corresponding figures for the resistant strain were 35 per cent., 45 per cent. and 16 per cent. respectively. On the other hand the susceptible strain showed a mortality of 40 per cent., when tested against the virus of louping-ill, as compared with a mortality of 60 per cent. in the resistant strain; so that the genetic factors concerned, whatever they may be, do not seem to operate against all types of infection, though they are operative against many.

Webster (1937) was later able to develop three strains of mice which he regarded as genetically stable in their reactions to *Salm. enteritidis* and to the virus of St. Louis encephalitis—one susceptible both to bacterium and virus, a second susceptible to bacterium but resistant to virus, and a third resistant to virus but not to bacterium. The resistance displayed by the animals resulting from various cross-breeds of these strains were in accord with the hypothesis that susceptibility to the two infective agents is regulated by two distinct sets of inherited factors (see also Church 1939).

Schütze, Gorer and Finlayson (1936), who have made tests on Webster's resistant and susceptible strains, record rather different results. The resistant strain showed a lower mortality than the susceptible when tested against *Salm. enteritidis* or *Salm. typhi-murium*; but when the two strains were tested against the pneumococcus, or against *Past. septica*, there was no significant difference in their behaviour. The discrepancy between these results and those recorded by Webster may be due to the fact that Schütze and his colleagues infected their mice by intraperitoneal injection, while Webster used the intranasal route. In Schutze's experiments both strains were equally susceptible to the virus of louping-ill.

We are still largely ignorant of the defence mechanisms whose effectiveness is determined by genetic constitution. Gorer and Schütze (1938) found some evidence that in a strain of mice resistant to *Salm. typhi-murium* the specific antibody response to the "H" antigen was better than in a susceptible strain, but this relation did not hold for "O" antigen, nor for the "H" or "O" antigens of *Salm. enteritidis*. Lurie (1941) on the other hand, working with inbred strains of rabbits, of low and high resistance, demonstrated that both the degree of cellular response to invasion by the bovine tubercle bacillus, and of skin response to the injection of heat-killed bacilli, was higher in the tuberculosis-resistant strains. (see p. 1299). In inbred strains of mice selected for resistance to *Salm. typhi-murium* the degree of resistance was found by Gowen and Calhoun (1943) to be correlated with the mean number of leucocytes circulating in the blood. A large number of circulating leucocytes, however, is probably a manifestation of a general not of a specific resistance to the organism, for, as Reich and Dunning (1941) showed in rats, the numbers of leucocytes may be correlated with general fitness for survival.

Severens, Roberts and Card (1944) studied the defence mechanism in two breeds of hen, which as chicks aged 1–10 days were respectively susceptible and resistant to infection with *Salm. pullorum*. All the demonstrable differences in the reactions of the two breeds were connected with lymphocytes. Age for age, the number of circulating lymphocytes, the rate of their normal increase after hatching, and the number present in the tissues of the spleen, were all greater in the resistant breed of chick. Moreover, splenectomy reduced both resistance and the circulating lymphocytes in the resistant chicks, but had little effect on the susceptible. The resistance was not due to a greater bactericidal power of the blood, although blood lymphocytes were observed to be phagocytic. It is suggested that the greater availability of lymphocytes may have increased the resistance by providing large numbers of precursors for macrophages in the tissues of the resistant chicks.

It would be unwise to expect that an increase in strain resistance would be determined by a change in a single group of mechanisms. For example, Hill, Hatswell and Topley (1940) bred mice from the survivors of a certain dose of the endotoxin of *Salm. typhi-murium*, and repeated the procedure for ten generations. The tenth generation was highly resistant to the toxin as compared with control unselected mice, but in spite of this it had not acquired any resistance to infection with the living bacillus.

Acquired Immunity.

It is with acquired immunity that we are here mainly concerned; and our interest lies particularly in those reactions that we can induce, and study, in the laboratory. Before discussing these mechanisms in any detail, it will, however, be well to consider briefly the general difference in behaviour displayed by immune and susceptible animals.

Grades of Immunity.

We have noted that the kinds of immunity in which we are most interested are seldom absolute. To keep our ideas clear and precise we may consider briefly the grades of immunity that can, in fact, be demonstrated, remembering always that they shade into one another by imperceptible degrees.

Fig. 236 gives, in diagrammatic form, a rough classification that will be sufficient for our immediate needs. It represents an infection of the invasive type, associated

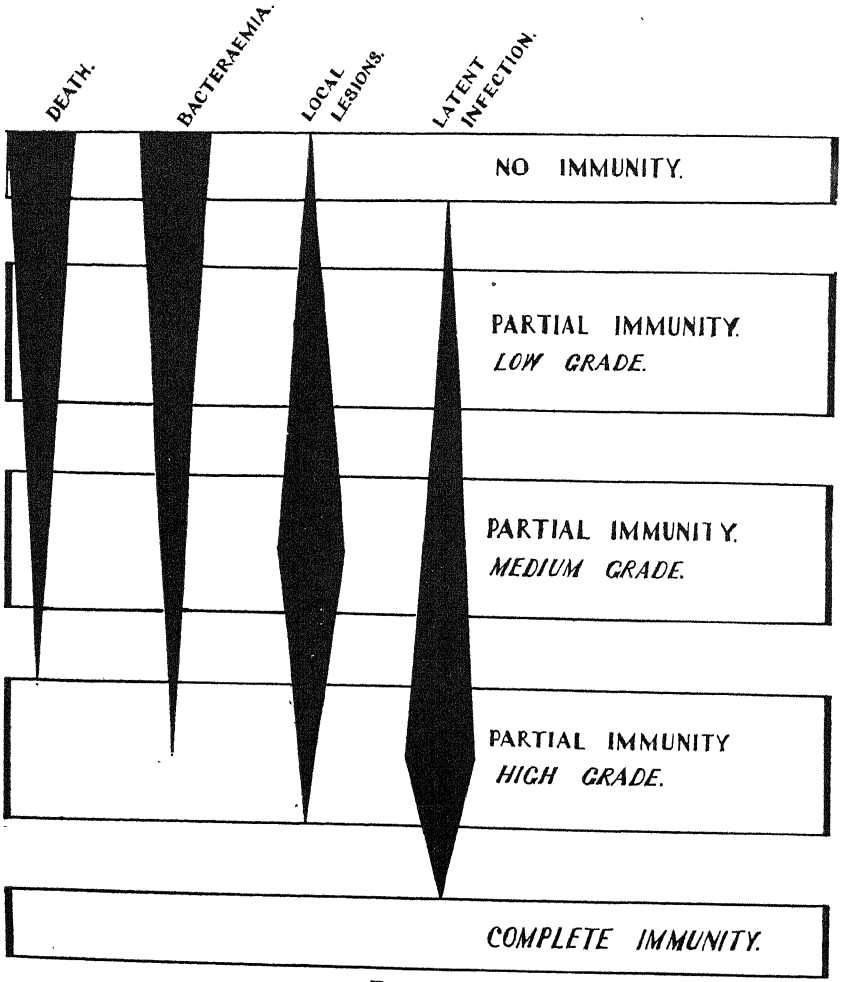

FIG. 236.

with a bacteræmia (an invasion of the blood stream by micro-organisms) as well as with local lesions; but it can easily be modified to meet the case of a toxæmic infection.

The width of the black wedge-shaped areas at any level may be taken to represent the chance of death, and the degree, or frequency, of bacteræmia, of local lesions, and of latent infections, in a sample of individuals possessed of approximately the same grade of immunity.

Thus, starting with the completely susceptible, we may assume that all, or almost all, infected individuals, will develop an acutely fatal bacteræmic infection. Local lesions will be infrequent, and minimal when they occur. There will be no latent infections.

Passing to our next arbitrary grade—partial immunity of low degree—we find fatal bacteræmic infections becoming less common, local lesions more frequent and more pronounced, and a small but increasing number of latent infections.

With partial immunity of a medium grade we find bacteræmia and death much less frequent, local lesions common and relatively extensive, and latent infections increasing in frequency.

With partial immunity of a high grade, death no longer occurs, bacteræmia is infrequent and, when it occurs, is slight and transient. Local lesions are becoming much less frequent and, when they occur, much less extensive. Latent infections reach a maximum frequency and then begin to decline.

Finally we reach the ideal—perhaps never fully attained—of complete or solid immunity. The host is entirely impervious to all attacks of the parasite.

It will not have escaped attention that the grades of resistance that we have labelled as partial immunity are compatible with severe and often fatal infections, and that many infective diseases in their common clinical form might be regarded as occurring in partially immune persons. This view is almost certainly the right one. The syndromes that normally characterize such diseases as typhoid fever, or lobar pneumonia, are expressions of partial immunity. They would not occur in a completely susceptible population attacked by a fully virulent parasite. The latter proviso is, of course, necessary. We may logically use the term immunity to express the relation of any given host to any given parasite, but events are determined by a balance—the balance between the virulence of the parasite and the resistance of the host.

The conception that infective disease, as we usually see it, is an expression of partial immunity, and that minor increases in immunity tend to increase the frequency of milder infections, is of sufficient importance to justify a few illustrative examples, drawn from experimental data.

It was noted by Smith and Moore (1892) that normal and actively immunized rabbits respond very differently to the subcutaneous inoculation of *Pasteurella septica*. Normal rabbits develop a rapidly fatal septicæmia. Immunized rabbits may develop large local abscesses, but show much less tendency to succumb to an acute generalized infection. More recent studies by Jones (1924) afford a good illustration of active immunity in all its grades. The normal rabbit is highly susceptible to *Pasteurella septica*, dying of a generalized septicæmia after the subcutaneous or intratracheal inoculation of 0·01 ml. of a broth culture. In the latter case pulmonary lesions are slight or absent. In rabbits partially immunized by a single injection of a killed vaccine a similar intratracheal injection of living culture is followed, in most cases, by a severe and fatal pneumonia, usually associated with a suppurative pleurisy and pericarditis. In rabbits immunized by repeated doses

of vaccine, intratracheal injections of living culture are usually without effect, while subcutaneous injections lead to the formation of localized abscesses followed by recovery.

Similar phenomena have been recorded in other bacterial infections. Thus Wadsworth (1904) found that the intratracheal injection of virulent pneumococci into normal rabbits was followed by a rapidly fatal septicæmia without local lesions, while similar injections in partially immunized rabbits were often followed by a characteristic pneumonic consolidation.

Differences of the same kind have been observed when strains of pneumococci of varying virulence have been injected intratracheally into normal rabbits. Thus Gaskell (1927) found that strains of high virulence gave rise to a rapidly fatal septicæmia without obvious pulmonary lesions; those of lower virulence to a fatal lobar pneumonia; those of still lower virulence to a patchy lobular consolidation, grading into an entire absence of reaction as the strains employed approached the region of complete avirulence.

The Relation of Immunity to Epidemiology and to Clinical Medicine.

Immunity is essentially an applied science. Its primary data are drawn from clinical medicine, and its outstanding achievement is that it enables us to do things, to interfere intelligently in the natural course of infective disease.

It must, therefore, remain in the closest touch with the field and with the ward. Its hypotheses, based largely on experiments in the laboratory, must stand their trial under field conditions. And here we are faced with a difficulty that is not shared by the more exact sciences. The relations of physics to the mechanical industries are superficially of the same kind as those of immunology to medicine, but actually they are very different. If a result obtained in the physical laboratory suggests a useful application to wireless reception or to aviation, or to any other practical and utilitarian end, it can be tried out with a reasonable certainty that its actual effect will be sufficiently obvious. It may succeed at once, or fail decisively at once, or succeed after adjustment; but in any case definite answers will come back from the field to the laboratory, and both parties to the transaction will learn something from their success or their failure. In medicine this is not always the case, simply because the practice of medicine is a much more difficult thing than any kind of mechanical industry, or indeed than any industrial process at all.

It may be quite easy to tell when an immunological procedure is an unqualified practical success. It is much more difficult to tell whether it is a partial success, or an unqualified failure. And this cause of confusion, which in truth affects the immunologist in the laboratory almost as much as the physician in the ward, is so important that it deserves a separate chapter.

CHAPTER 43

THE MEASUREMENT OF IMMUNITY REACTIONS IN THE LIVING ANIMAL

It is impossible to understand the present position of immunology, with its mixture of established fact, half-knowledge, hopeful guessings and frank bewilderment, without an adequate grasp of the difficulties involved in measuring immunity reactions in the living animal, and in assessing the significance of such measurements when they have been obtained.

That these difficulties should have been overlooked by the pioneers is not altogether surprising. The effects demonstrated in many of the earlier experiments were so dramatic as to need no exact measurement to establish their significance. The need for standardizing antitoxic sera did, indeed, provide an obvious opportunity for developing adequate biometrical methods; but the need was not realized, for reasons that will become apparent later in this chapter, and the opportunity was allowed to pass. As new methods of immunization were developed and tested in the laboratory, in the ward and in the field, the publication of violently conflicting reports as to their efficacy showed that something was amiss; but the remedy was not obvious, at least to the immunologist. The barriers that separate the different departments of science are not easy to break down, especially when the roads by which these departments are entered diverge widely in their course and are hedged by very different intellectual disciplines. It was natural enough that the laboratory worker and the clinician should show little eagerness to learn and apply the methods devised by the statistician. But the result has been a quite unnecessary amount of confusion; and the confusion is likely to persist so long as the need for such methods is ignored. It will not, therefore, be extravagant to devote a chapter to a brief discussion of the ways in which some of our present difficulties may be overcome—by avoiding the need for statistical methods where this is possible, and by using them intelligently when they cannot be escaped. It will be necessary to refer to many of the reactions that will be discussed in detail in later chapters; but, for the moment, their exact nature and significance does not concern us—we are regarding them merely as things that can be measured.

It is obviously beyond the scope of this book to describe, even in outline, the technical details of statistical measurement or even to give an easy and satisfactory account of the principles upon which such measurement is based. The student is advised to refer to one of the excellent textbooks available, such as those of Yule and Kendall, of Pearl (on the more purely medical side), of Fisher (on the laboratory and experimental side), and for a general conspectus of the subject to the smaller primers of Woods and Russell or of Hill. We must confine ourselves

here to a brief discussion of some general principles, with illustrative examples drawn from a few immunological problems.

The cause of our troubles is sufficiently obvious. It has been set out very clearly by Greenwood (1924) and by Yule (1924). The worker in the more exact sciences can reduce his uncontrollable variables to a minimum, or eliminate them altogether, and can so obtain constantly reproducible results. We cannot. In experiments on living animals, and still more in assessing the value of therapeutic or prophylactic procedures in man, we cannot exclude the interplay of factors about which we know little, except that they are certainly very numerous and may be very important. We cannot avoid an element of randomness in our observations; but, if we have planned our experiments wisely and fortune has been kind in eliminating major disturbing factors that we could not have foreseen, this randomness will be of the kind that determines the number of heads and tails observed in a hundred tosses of a coin. The effect of such random variation can be calculated, and hence allowed for; it is the assessment of the necessary allowance in any particular case that is our main concern.

It will simplify discussion to consider in turn a series of problems of the kind that are continually presenting themselves for solution.

THE MEASUREMENT OF RESISTANCE

To take the most obvious problem, though not the simplest, how can we measure the resistance of an animal to a particular parasite or to its toxin? Suppose first that we wish to measure directly the resistance of the animal as a whole, taking death or survival as our test. Then it is only under quite exceptional conditions that we can obtain *any* measurement on a single animal. If we are dealing with a very powerful toxin that kills rapidly, within a few minutes or hours, it is sometimes possible to give repeated and increasing doses at short intervals and so to measure approximately the amount which is necessary to cause death. But if our toxin acts more slowly, or if we are dealing with a living bacterium, this method cannot be employed. If we start with a small dose and the animal fails to die during the period—usually measured in days—within which we should expect death to occur, we cannot test it again by giving a larger dose, because our first dose will almost certainly have changed its resistance. It is not, from our present point of view, the same animal as before. If we start with a large dose and the animal dies, we do not know how it would have reacted to a smaller dose; if it lives, we know that it is resistant at that particular dose level, but we do not know and can never discover how it would have reacted to doses larger still. It is clear that, if we take death or survival as our test, we must deal with groups not with individuals. This condition is, in truth, usually implicit in the question we want to ask. We are not often interested in the resistance of a particular mouse, or guinea-pig, or rabbit, as such. We are almost always regarding the individual as a representative of a class—normal, or treated in some way that may, we think, have altered resistance to a particular bacterium or toxin—and we are none of us naïve enough to believe in a standard guinea-pig, even if we confine ourselves to animals of a given breed, sex, age and weight. What we sometimes fail to realize is that we must, in most cases, test large numbers of animals before we can regard our result as representing truly the average behaviour of the class from which those animals are drawn.

There are occasions, however, on which we do want to measure the resistance of an individual man or animal; and, before discussing the methods to be adopted in measuring the resistance of groups, we may consider whether there is any way of solving this particular problem.

The Measurement of the Resistance of an Individual.

We cannot, as we have seen, obtain a direct measure of the resistance of any individual animal as a whole; but we can sometimes measure the resistance of a particular tissue, provided that it is possible so to localize the effect of any one inoculum that the reactions to several inocula can be observed simultaneously. This method is commonly exploited in the determination of skin sensitiveness to bacterial toxins. The local effect of a small intradermal inoculation—0·2 ml. is a convenient amount—is limited to the near neighbourhood of the site of injection. By spacing injections so as to leave a few centimetres between them it is easy to test several dilutions of a toxin on a comparatively small area of skin. In this way we can obtain an approximate measure of the smallest dose of toxin that will yield a characteristic reaction, and we can regard this as a measure of resistance—the smaller the dose that will produce such a result the less the resistance of the person or animal under test. Sometimes we rely on a different kind of skin test—the allergic—in which a positive reaction indicates not susceptibility but resistance, showing an increased energy and rapidity of response to a particular bacterial product.

There is another way in which we may attempt to estimate individual resistance—the demonstration and measurement of specific antibodies in the blood. In some cases we may measure the protective power of the serum against a toxin, or a virus, or occasionally against a living bacterium; but this involves further tests on animals, so that we are faced with the same problem as before. Alternatively we may make use of *in vitro* antibody reactions—agglutination, complement fixation, the bactericidal power of the whole blood, and so on. But our measurement of resistance is now becoming very indirect, and we must watch our assumptions with corresponding care.

All these indirect methods of measuring *individual* resistance are, in fact, dependent on a preliminary knowledge of *average* behaviour. We cannot accept our skin tests, antitoxin titrations, agglutination reactions, and so on, as evidence of immunity until we have shown that such a correlation exists; and, to establish the existence of this correlation, we must study the behaviour of groups.

The Measurement of the Average Resistance of a Group.

Let us start with the simplest problem. How can we determine whether a given procedure has made any difference at all in the resistance of a group of animals, even without measuring how large that difference is? If the increase in resistance is of a very high order, our task is easy. We have only to administer to our treated animals a large dose of bacteria or toxin, which experience has shown to be certainly fatal to all untreated animals of the same species, age, weight, etc., and note that the treated animals survive. But we shall be wise to make very sure about our "certainly fatal" dose, especially if our group of treated animals is small. We shall, indeed, always test a few untreated controls to guard against any gross experimental error.

But the increase in resistance may not be of this dramatic kind. Our treated

animals may be unable to withstand a dose of bacteria or toxin that will kill *all* untreated controls, though the mortality in treated and untreated groups may differ appreciably. Our problem is to determine whether this observed difference is likely to have occurred as the result of chance.

One method is to calculate the chances directly by straightforward but laborious arithmetic.

Suppose that we know, from an extended experience, that a particular experimental procedure causes a certain average death rate among large groups of animals. Let us express this death rate as p, using a decimal instead of a percentage notation (*i.e.* expressing a 50 per cent. death rate as 0·5). Then p will also be the chance of any particular animal dying. We should, in other words, expect to get death and recovery equally often if we made a series of tests, each on a single animal. Any animal under test must either live or die, so that, if the chance of death is p, the chance of life is q, where $q = 1 - p$. Expressed in figures, if the chance of death is 0·3 the chance of life must be 0·7; or, to revert to our more familiar percentages, if the percentage mortality is 30 the percentage survival must be 70.

If we know the true average mortality rate, or chance of death, how often are we likely in any single test to meet with a death rate that differs from the average death rate by any specified amount?

Suppose we make an experiment on two animals. Let us call them A and B. Using the notation referred to above, A's chance of dying is p. If A dies, B may either live or die; and B's chance of death is also p. So the chance of both A and B dying is $p \times p$ or p^2. The chance of both A and B living is clearly q^2. The chance of A living and B dying is $p \times q$; and this is also the chance of A dying and B living. So the chances of one animal dying and the other living, irrespective of which does which, is $2pq$. We have therefore:

Chance of two deaths	p^2
Chance of one death	$2pq$
Chance of no death	q^2

These are the successive terms of the expansion of the expression $(p + q)^2$, and we can deal in exactly the same way with a group of any size, by substituting the number of animals in the group for the 2 in the expression given above. For instance, if we had four animals in a group, our expression would become $(p + q)^4$ and the chance of getting 4, 3, 2, 1 or 0 deaths in any single test would be p^4, $4p^3q$, $6p^2q^2$, $4pq^3$ and q^4 respectively.

To take a numerical example, if our p were 0·5, representing an average 50 per cent. mortality, our q would also be 0·5, and our expression would be $(0{\cdot}5 + 0{\cdot}5)^2$ for 2 animals and $(0{\cdot}5 + 0{\cdot}5)^4$ for 4 animals. Working these out, our chances of getting 0, 1 or 2 deaths with 2 animals are 0·25, 0·5 and 0·25 respectively. Our chances of getting 0, 1, 2, 3 or 4 deaths with 4 animals are 0·0625, 0·25, 0 375, 0·25 and 0·0625 respectively. The figures represent the relative frequencies of each of the 5 possible events expressed as a fraction of unity. That is, if the experiment of infecting four similar mice with a 50 per cent. killing dose were to be repeated N times, we should expect to get no deaths on 0·0625 N occasions, one death on 0·25 N occasions, and so on. In Fig. 237A these relative frequencies have been plotted vertically on a base line divided equally to represent the 5 possible events. We may calculate the frequencies in the same way for groups of any size, expanding the expression $(p + q)^n$, where n is the number of animals used. B and C represent the figures for $n = 8$ and $n = 12$. As n increases, the figure becomes less step-like, and shows a decreasing proportion of its total area at each end of the base line. We may note that the figures represent distributions of the relative frequencies of the various possible events. The first important fact about a frequency distribution is the average, or mean, frequency, which is used to characterize the distribution. In

A, B and C the mean frequency is in each case $n \times 0{\cdot}5$, *i.e.* 2, 4 and 6 deaths respectively. The other frequencies are symmetrically disposed on either side of the mean. (The symmetrical disposition is the result of taking $p = q$. If we take $p = 0{\cdot}3$, and therefore $q = 0{\cdot}7$, the relative frequencies of 4, 3, 2, 1 and 0 deaths in a batch of 4 mice are given by the binomial expansion of $(0{\cdot}3 + 0{\cdot}7)^4$, and are respectively 0·0081, 0·0756, 0·2646,

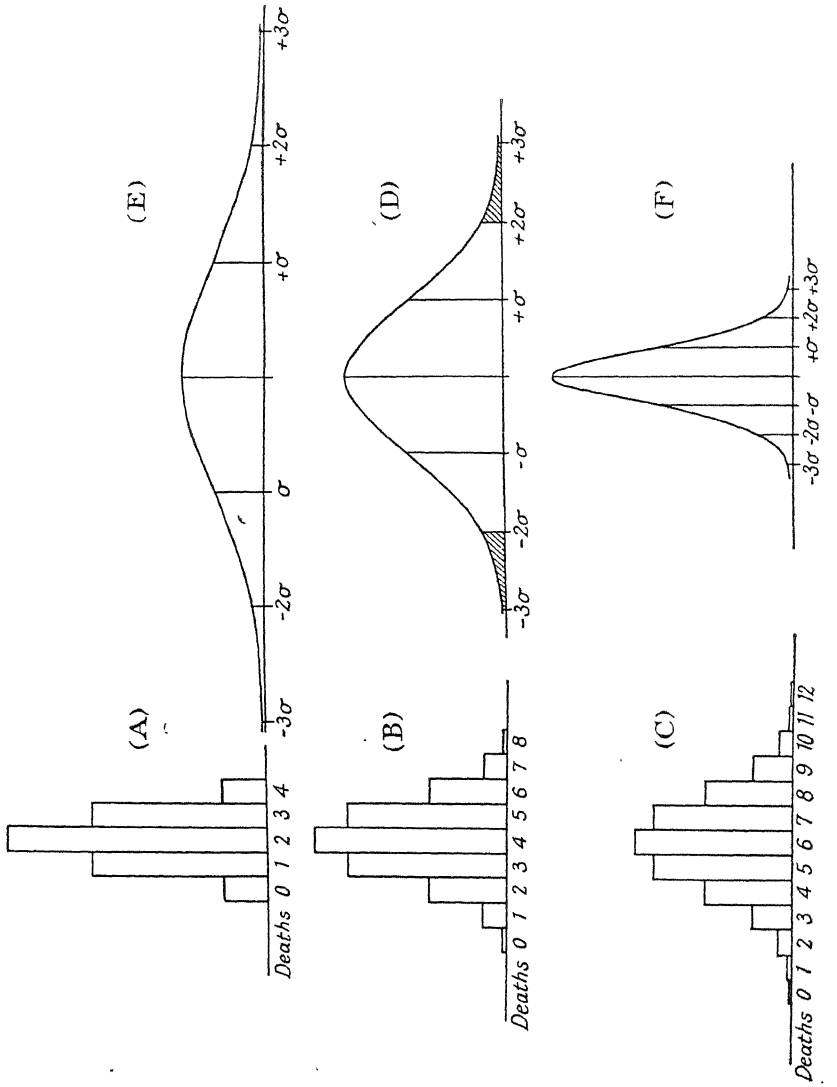

FIG. 237.

0·4116 and 0·2401. Here the distribution is not symmetrical; 1 death in four will occur with the highest frequency, and the mean death rate in 4 mice is 1·2).

Frequencies other than the mean frequency are conveniently recorded as *deviations* from the mean value. In A, for example, the death rates of 3/4 and 1/4 are regarded as deviations of + 1/4 and − 1/4 respectively from the mean death rate of 2/4; or,

expressed in percentages, as deviations of + 25 per cent. and − 25 per cent. from a mean of 50 per cent.

In experimental work we have often to compare death rates in several sets of animals differing in size and (see p. 997) in the resistance of the individual members. It is clear that the 3 groups in A, B and C are not fully comparable, even though all the animals are, by hypothesis, equally susceptible to the lethal agent. In A, for example, the frequency with which a deviation of + 50 per cent. from the mean will occur by chance is p^4, which is 0·0625 or about 6 times in 100 trials; whereas in C, the same deviation will occur by chance about twice in 10,000 trials, since p^{12} is 0·000244. More generally, as the relative heights of the columns in A and C show, the bigger deviations from the mean are less likely to occur in the test with the larger number of animals; and there is a greater probability of obtaining results near the expected mean death rate of 50 per cent. In comparing distributions, then, we must consider not only the mean, but also the range over which the deviations from the mean are spread; to do this we need a measure of the spread of deviations applicable to all distributions of this type. This measure we find in a value known as the standard deviation, which is the second important characteristic of a distribution.

TABLE 60

Deviation in Terms of the Standard Error; or Ratio between a Difference and its Standard Deviation.	Odds against this Deviation or Difference being the Result of Random Chance.
0·5	0·6 to 1
1·0	2·15 to 1
1·5	6·5 to 1
2·0	20·98 to 1
2·5	79·53 to 1
3·0	369·4 to 1
3·5	2,149 to 1
4·0	15,773 to 1
4·5	147,188 to 1

For the better appreciation of the standard deviation, we shall consider a distribution that is more general in form than A, B or C. These are step-like, being made up of a collection of parallelograms, the area of each of which corresponds to the frequency of each event. If we make n very large, say 1,000, and reduce the scale upon which we record the events, the figure for $(p + q)^{1000}$ approximates to a continuous curve of the form D. This curve is known as the *normal curve*. The distribution of frequencies of a great many biological measurements, such as the height of human beings of a certain age, or the resistance of a certain type of animal to doses of a certain poison, approximates to this mathematically defined curve. For reasons that will be found in the statistical text-books, we may assume with some confidence that in the measurements of resistance, etc., with which we are mainly concerned in immunity, the deviations from a mean value will be distributed much as they are in the normal curve, and that the arithmetic of the normal curve will be applicable to most of our data.

The standard deviation of a distribution that approximates to the normal may be obtained arithmetically, by squaring all the deviations from the mean, adding the squares together, dividing the result by the total number of observations, and taking the square root. The resulting figure, the "root mean square deviation," is usually written as σ. It has a positive and a negative value and is correspondingly measured to the right and left of the mean in graphic representation of the distribution. In D, for example, the base line has been marked off at $\pm\sigma$, $\pm 2\sigma$ and $\pm 3\sigma$, and verticals erected at these points. It will be seen that nearly all the events or observations summarized by the curve are included between the limits $\pm 3\sigma$. In fact, only some 0·027 per cent. of the observations lie outside $\pm 3\sigma$, and only about 4·5 per cent. outside $\pm 2\sigma$. Figures E and F, representing

normal curves in which the distribution of frequencies is respectively narrower and wider than that in D, are also divided in this manner, and it is obvious that the areas in D, E and F marked off by the verticals erected at multiples of the standard deviation in each case bear the same relation to the total area enclosed by the curve.

Now since the frequencies of *all* the events or observations are represented by the total area enclosed by the curve, we may express the chance of observing one of a given set of these events by the ratio of the area representing the set of events to the total area. Suppose we wish to know the chance of observing events whose frequencies deviate from the mean by more than $+ 2\sigma$. In Fig. 237 D it is clearly the ratio of the shaded area on the right of the vertical erected at $+ 2\sigma$, to the total area. This ratio is 1 : 43 96 ; or, as we shall find it more convenient to say, the odds against observing events of this nature are 42·96 to 1. The chance of observing a deviation greater than $+ 2\sigma$ and less than $- 2\sigma$ is in a similar way the ratio of the sum of the shaded areas at each end of the figure to the total area. Since the curve is symmetrical, the two shaded areas are equal, and the ratio is 2 : 43·96, or 1 : 21·98 ; that is, the odds are 20 98 to 1 against deviations greater than $\pm 2\sigma$. These odds have been calculated for all multiples and submultiples of σ in the normal curve and they are tabulated in Table 60 for values of σ from 0·5, 1·0, 1·5 . . . to 4·5. Beyond 4·5 the odds are so high that their exact value is of no interest.

In the particular cases with which we started, we may calculate the standard deviation as indicated above. There is a simpler method of calculation, however, applicable to these and any other distributions that are assumed to arise from the binomial expression $(p + q)^n$. The standard deviation is in fact equal to $\sqrt{npq}$. Applying this to distributions A, B and C in Fig. 237 we have

Distribution.	Mean.	Standard Deviation.
A. $(p + q)^4$	2 deaths	$\sqrt{1} = \pm 1$ death
B. $(p + q)^8$	4 deaths	$\sqrt{2} = \pm 1{\cdot}414$ deaths
C. $(p + q)^{12}$	6 deaths	$\sqrt{3} = \pm 1{\cdot}732$ deaths

Or if we regard mean and standard deviation as proportions, the latter becomes $\sqrt{\frac{pq}{n}}$ and the result is

Distribution.	Mean.	Standard Deviation.
A. $(p + q)^4$	0·5	$\pm$ 0·250
B. $(p + q)^8$	0·5	$\pm$ 0·177
C. $(p + q)^{12}$	0·5	$\pm$ 0·144
D. $(p + q)^{1000}$	0·5	$\pm$ 0·016

Suppose that we apply to 12 animals a test that will, on the average, kill 50 per cent. of them, what are the odds that we shall observe a mortality of 83·3 per cent. ? In this case $\sigma = \pm 1{\cdot}732$ deaths. An 83·3 per cent. mortality corresponds to 10 deaths, a deviation from the mean of + 4. This deviation differs from the mean by 4/1·732 times (= 2·31 times) the standard error. As we see from Table 60, the required odds lie between 21 to 1 and 80 to 1. In terms of proportions, the deviation is 0·83 − 0·5 = + 0·33 and this in terms of the standard deviation is 0·33/0·144, which as before is 2·31.

The applicability of the arithmetic of the normal distribution to our test animals depends on how our experimental data approximate to the curve.

In the kind of experiments with which we are usually concerned there are two factors that affect this degree of approximation. One is the number of animals we use. We shall never use enough to give us a really smooth curve. In fact our distribution will usually be nearer to that shown at C, Fig. 237, than to the true normal curve. The other factor is that while the normal curve is symmetrical, corresponding to the expansion of $(0{\cdot}5 + 0{\cdot}5)^n$, the curve with which we are actually concerned will usually be asymmetrical, corresponding, for example, to the expansion of $(0{\cdot}3 + 0{\cdot}7)^n$, for we shall not necessarily be dealing with a test that gives an average mortality of 50 per cent. But if the number

of animals in the group under test is not too small, say not less than twenty, and the chance of the less likely event, life or death whichever it may be, is not less than 0·2, the odds calculated on the basis of the standard deviation are sufficiently accurate.

It will, however, have been noted that we have, throughout the preceding discussion, assumed the possession of one very important piece of knowledge—the true average mortality involved in the procedure under test. Usually we do not know this. The question that faces us is far more often as follows : In a particular test we have observed a mortality of, let us say, 40 per cent. among a group of 30 animals. What are the odds, if we did exactly the same experiment over again, that we should, in this second test, observe a mortality of 60 per cent. or more ? The only assumption on which we can proceed in this case is that our observed 40 per cent. mortality is the true average mortality ; but it is by no means a safe assumption, and for that reason among others we shall be wise to suspect that the real odds are shorter than those we calculate.

So far we have been concerned with a single group of animals. But in most of our experiments we shall be comparing the reactions of two groups of animals treated in the same way except for the procedure under test, which is applied to the test group, the other being observed as a control. If the mortality rate in the two groups is different, we wish to know whether this difference might have arisen by chance in two groups that were in fact similar, or whether the odds against a chance effect are large enough to rule it out. If the groups are not different then the most likely event is a difference of 0. But the results from each group may by chance vary round the mean, and if one result happens to deviate largely in the positive direction and the other in the negative, the chance difference may be large. If we repeated the comparison many times, we should expect the larger chance differences to be infrequent, the smaller ones more frequent, and differences of 0 to be most frequent. Now it is found that *differences* between pairs of mean values derived from two normal distributions are themselves distributed normally ; and this distribution of *differences* has a standard deviation, or as it is usually called, a standard error. This standard error is easily obtained, since it is the square root of the sum of the squares of the standard errors of the two means from which the difference was derived. In our simple binomial examples, where x_1 and x_2 are the numbers of animals dying in the two groups, the standard error of a mean proportional death-rate x_1/n_1 found in a group of n_1 animals in which the expectation of death is p_1 is $\sqrt{p_1q_1/n_1}$, and similarly of x_2/n_2 is $\sqrt{p_2q_2/n_2}$. The standard error of the difference $x_2/n_2 - x_1/n_1 = d$, is then

$$\sqrt{p_1q_1/n_1 + p_2q_2/n_2}.$$

Now if the difference has arisen by chance, *i.e.*, the two groups do not differ in any significant way, the best measure we have of the real chance of death is the death rate in the 2 groups as a whole. This, the mean chance of death, is $(x_1 + x_2)/(n_1 + n_2)$, which we may call p_0. The mean chance of survival, $q_0 = (1 - p_0)$. The standard error, then, of the mean x_1/n_1 is now $\sqrt{p_0q_0/n_1}$ and that of x_2/n_2 is $\sqrt{p_0q_0/n_2}$; and the standard error of the difference is $\sqrt{p_0q_0\left(\frac{1}{n_1} + \frac{1}{n_2}\right)}$ or if we are dealing in percentages

$$100\sqrt{p_0q_0\left(\frac{1}{n_1} + \frac{1}{n_2}\right)}$$

Let us now take a concrete example. Thirty mice that had been repeatedly inoculated with a killed suspension of *Salm. typhi-murium* and 30 uninoculated mice to serve as controls were injected intraperitoneally with a constant dose (1,000 bacilli) of living *Salm. typhi-murium*. They were then observed over a period of 28 days. During this time 16 of the 30 vaccinated mice died of the infection, and 29 of the 30 controls. The survivors were killed on the 28th day and cultures were taken from their spleens. *Salm. typhi-murium* was recovered from 10 of the

14 surviving vaccinated mice, but not from the one surviving control. We may tabulate these results as follows:

Number of mice surviving on 28th day:

Vaccinated	14 = 46·67	per cent.
Controls	1 = 3·33	,, ,,
Difference	13 = 43·34	,, ,,

Number of mice showing no evidence of infection (completely resistant):

Vaccinated	4 = 13·33	per cent.
Controls	1 = 3·33	,, ,,
Difference	3 = 10·00	,, ,,

The vaccinated mice show an advantage over the controls of 43·34 per cent. in regard to survival rate, but of only 10 per cent. in regard to their ability to resist completely the injection of this number of organisms. What are the odds against each of these observed differences in behaviour having been due to chance?

Of 30 vaccinated mice 14 survived: of 30 control mice 1 survived.

$$q_0 = \frac{14+1}{30+30} = \frac{15}{60} = 0{\cdot}25$$

$$p_0 = 1 - q_0 = 0{\cdot}75$$

$$\sqrt{p_0 q_0 \left(\frac{1}{n_1} + \frac{1}{n_2}\right)} = \sqrt{0{\cdot}75 \times 0{\cdot}25 \times \left(\frac{1}{30} + \frac{1}{30}\right)}$$

$$= \sqrt{\frac{0{\cdot}75 \times 0{\cdot}25}{15}} = 0{\cdot}1118$$

The standard error then of differences that might arise by chance expressed as a percentage is $\pm$ 11·18, and the distribution of the possible chance differences round an expected mean difference of 0 per cent. may be represented as in Fig. 238.

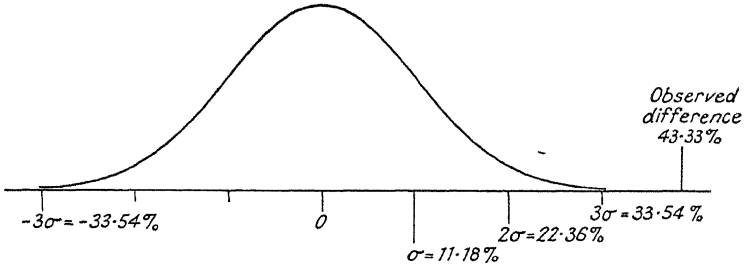

FIG. 238.—Showing the hypothetical frequency distribution of the chance differences between means of two samples derived from the same population.

Since chance differences may be either positive or negative, the observed difference must be considered as $\pm$ 43·34. The position of + 43·34 is recorded in the figure; that of — 43·34 will clearly lie a similar distance left of the O value. In both cases the difference is 3·87 times the standard error. By reference to Table 60 we find the odds against observing such a difference as this as the result of chance lie between 2,149 to 1 and 15,773 to 1; they are in fact 9,190 to 1. These are very long odds, so that we shall conclude with considerable confidence that we have

increased the ability of our mice to withstand the test dose of bacteria, by our preliminary injections of killed bacteria.

Have we increased their ability to resist the test dose completely ?

Of the 30 vaccinated mice, 4 proved completely resistant; of the 30 control mice 1 proved completely resistant.

Taking q to express resistance—

$$q_0 = \frac{4+1}{30+30} = \frac{5}{60} = 0{\cdot}0833$$

$$p_0 = 1 - q_0 = 0{\cdot}9167$$

$$\sqrt{p_0 q_0 \left(\frac{1}{n_1} + \frac{1}{n_2}\right)} = \sqrt{\frac{0{\cdot}0833 \times 0{\cdot}9167}{15}} = 0{\cdot}07136.$$

The observed difference in the proportion of mice completely resistant is 10·00 per cent., the standard error expressed as a percentage is 7·136. The observed difference is 10/7·136 (1·4) times its standard error.

Turning to Table 60 we find that the odds against observing such a difference as this as the result of chance are about 5 to 1. These are very short odds; and we should clearly place no confidence in them. Taking our observations as a whole we should conclude that, by the method of immunization employed, we had almost certainly increased the ability of our mice to survive the test dose of living bacteria, but that the effect on their ability to resist infection entirely was relatively slight, and quite possibly insignificant.

This is one selected example. It may be useful to note how the odds vary according to the number of deaths or survivals observed in two groups, each of 20 animals, one group being treated by some procedure under test, the other serving as untreated controls. Both groups, of course, will be subjected to the same dose of living bacteria, toxin or other agent against which the treatment is directed. These odds are shown in Table 61, very short odds being neglected and odds of over 1,000 to 1 being no further specified. No odds are shown for less than 5 deaths in one group or more than 15 deaths in the other group. Where the number of animals in each group is as small as 20, and the number of deaths in each group is very small (say 4 or less) or very large (say 16 or more) the assumptions on which these calculations are based no longer hold. The example of the fully resistant mice among our groups of 30 was not above criticism in this respect.

In all the examples discussed above we have assumed that, so far as chance has entered into our observations at all, it has been in the form known to the statistician as " the error of random sampling " ; but there are other kinds of " chance," using that term in a broader and less technical sense. To take a crude example, suppose that we were testing a method of immunizing rabbits against a particular toxin, and failed to allow for the fact that different breeds of rabbit may differ significantly in their resistance to any agent of this kind. We might include in our " treated " group a majority of animals of the more resistant breed, and in our control group a majority of animals of the more susceptible breed. Under these conditions our " treated " group would probably show a statistically significant advantage, even if our treatment had, in reality, been quite without effect. " Chance " would be a charitable term for this particular piece of experimental carelessness ; but other factors, not nearly so obvious as differences in breed, or age, or sex, may influence the reaction of our experimental animals to the test

we are employing. An essential part of a good experimental technique is, as Fisher emphasizes, that all possible means shall be used to "randomize" the conditions of test, *i.e.* to reduce the unknown variables to influences of the same type as those that determine whether a tossed coin shall come down "heads" or "tails."

It is of interest to inquire how far we can do this in practice. Not many workers have taken the trouble to test their technique in this way, but Lockhart (1926) records observations bearing directly on the point at issue. In each of four experiments, several groups of 20 mice were injected with the same dose of the same culture of a pathogenic organism (*Salm. typhi-murium*) and the number dying in each group during the succeeding 14 days was noted. In one experiment 9 groups were injected; the deaths were 16, 16, 17, 19, 18, 17, 15, 17 and 14. This gives 36 differences between pairs. The difference between 14 and 19 deaths, the largest observed in this group, should, as will be seen from Table 61, occur on the average once in 27 comparisons. In a second series of 5 tests the deaths were 18, 17, 13, 16 and 13; this gives 10 differences between pairs. The difference between 13 and 18 deaths would be expected to occur, on the average, once in 17 comparisons.

In a third series of 5 groups the deaths were 5, 2, 4, 3 and 5; there is here no difference that would not be expected on our assumption, but the death rate is very low in all groups. In a fourth series of 5 groups the deaths were 19, 20, 19, 20 and 19; there is no unexpected difference, but the death rate was very high in all groups. Such a series of tests may be regarded as a trial of the adequacy of our experimental methods. If the distribution of deaths actually observed in different groups that have, within the limits of experimental control, been subjected to exactly the same treatment agrees closely with that expected on the assumption that the only differences that occur will be those due to the error of random sampling, then our technique may be regarded as highly satisfactory. If our observed distribution differs widely from that expected, then we have not succeeded in eliminating other disturbing factors, of unknown nature, which may mislead us when we come to apply a known procedure to one group in order to test its effect.

Lockhart's figures suggest that he was reasonably successful in randomizing his experimental conditions. It is, however, doubtful whether equally satisfactory results can always be attained in immunological tests of this kind, and it will perhaps be wise to make a practice of demanding rather long *calculated* odds before accepting an observed difference in behaviour as statistically significant. We might, for instance, fix an arbitrary limit for the ratio of a difference to its standard error at 3 : 1, which would give us calculated odds of 369 to 1 against the observed difference being due to chance. These odds, may, of course, be too high, and might lead us to ignore differences that are possibly significant. But if we adopt lower odds we may attach significance to differences that are in fact meaningless. In dealing with observations from the ward, or from the field, where fresh data cannot quickly or easily be collected, it is desirable that attention should be drawn to any points of possible interest or importance, with due emphasis where necessary on the allowance that must be made for sampling errors. In experimental work the case is rather different. The investigator will clearly be wise to take any hint that is offered by his quantitative results; but if he desires to publish his findings and draw conclusions from them, it is reasonable to insist on a stricter standard. There is nothing to prevent him from repeating any experiment that has given a statistically dubious answer; and this is clearly what he should do.

Experiments should, indeed, always be repeated, even when a single trial has given a result that passes all the conventional tests of statistical significance. The

single trial cannot, except by analogy, tell us anything about happenings outside its own particular conditions; and we can never be quite sure that these conditions do not include some determining factor other than that, the effect of which we are trying to investigate. By repeating an experiment several times, we are testing, in the only way we can, for the intrusion of unknown factors other than errors of random sampling. If each of several tests gives us a statistically significant answer, and each answer points in the same direction, we shall have some justification for stating our conclusion in general as opposed to particular terms; but if some tests give different answers from others we must solve the problem of why these differences occur before we can accept the indication given by the original experiment.

The question thus arises, assuming a limit to the number of experimental animals that we have available, how we can use them to the best advantage in solving any particular problem. Shall we carry out one, or two, experiments with large numbers of animals in our test and control groups? or, shall we make several experiments, each on a smaller scale?

The answer would seem to be that each test should be made on a number of animals sufficiently large to enable us to detect a difference of the order we are expecting, making allowance for errors of random sampling. When this point has been reached we shall gain more by repeating the experiment, using groups of a similar size, than by doing one very large experiment, in which the effect of sampling errors would be considerably reduced, but which would give us no information in regard to other intrusive factors.

In most laboratory experiments, in which we are expecting a high mortality, usually approaching 100 per cent., in our control group, and are hoping for a much lower mortality, say 30–60 per cent., in our treated group, we shall gain more information by repeating our experiment six times, using 25 animals in each group, than by doing one experiment with 150 animals in each group. The best procedure, in any given case, will depend on the size of the difference we are expecting. Sometimes, particularly in the application of a therapeutic measure in human disease, quite a small difference in mortality is an objective well worth attaining; and, if we wish to determine a difference of this size, our groups in any individual trial must be relatively large.

Let us take a concrete example. Certain laboratory experiments have led to the production of a serum which, on *a priori* grounds, may be expected to have some curative influence on a particular infective disease. Like all new curative measures it *must* be subjected to a period of trial before it is adopted for routine use. Our expectations may not be realized. The serum may be quite useless in practice. It is not a question of trial or no trial, but of a well-planned trial that will give us a definite answer as quickly as possible, as against a planless, haphazard series of trials that will take a long while to tell us very little, perhaps at a considerable expense in lives. Let us suppose that the real average effect of the serum is to reduce the case mortality of the disease from 30 per cent. to 20 per cent. —not, perhaps, a dramatic result but one that will save a large number of patients if the disease is a prevalent one. The only way in which the existence of such an effect can be quickly and certainly established is to test the serum on an adequate group of cases and compare the mortality in this treated group with the mortality in an untreated group. The two groups must if possible be compared over the same period of time and in the same place, since the case mortality of almost all

acute infective diseases fluctuates from time to time and from one locality to another. They must also be similar in all relevant respects other than the administration of the serum; for example, they must all be of the same race, and the age and sex distribution within the two groups must be approximately the same. Let us see what will happen if such a trial is carried out on two groups, each containing 10, 50, 100, 150, 200, 250 or 500 patients. The relevant figures are set out in Table 62, the standard error being calculated on the percentage basis.

TABLE 62

SHOWING THE RATIO [DIFFERENCE IN MORTALITY/S.E.] FOR TREATED AND UNTREATED GROUPS IN THE CASE OF AN ANTISERUM WHICH PRODUCES A DECREASE IN CASE MORTALITY FROM 30 PER CENT. TO 20 PER CENT.

Number in Each Group.	Deaths in Treated Group.	Deaths in Untreated Group.	Difference. per cent.	S E.	Difference in Mortality — S.E.
10	2	3	10	19 365	0·52
50	10	15	10	8 660	1·15
100	20	30	10	6·124	1·63
150	30	45	10	5 000	2 00
200	40	60	10	4·330	2·31
250	50	75	10	3·873	2·58
500	100	150	10	2·739	3·65

Quite clearly a trial with 10 treated and 10 untreated patients is useless. In different trials on this scale, one observer will record more deaths in the treated group, another in the untreated. There will be hopeless confusion. The position with groups of 50 treated and 50 untreated patients is not much better. In about one of every four trials a difference such as this would be observed as the result of chance alone. There will be sharp differences of opinion as to whether the treatment does *any* good, and no possibility of assessing even approximately how much good it does. As the number of patients in each group increases the significance of the result recorded also increases—not proportionately to the number itself but in proportion to its square root. After a trial on two groups each of 100 patients we should begin to think it probable that the serum had done some good. After a trial on two groups each of 200 patients we should be inclined to adopt this view as a provisional conclusion pending further evidence. If trials on this scale were repeated we should be surprised if there were many unfavourable reports. After a trial on two groups of 500 patients we should have no reasonable doubt that our serum had reduced the case mortality. Moreover, with groups of this size we should begin to think that the benefit to be expected from our serum was appropriately represented by a decrease in case mortality from about 30 to about 20 per cent.—that is, by a saving of one patient in three who would otherwise have died—since the chance of the observed decrease differing from the real average by any given amount grows less and less as the number in the group increases.

It is of very real importance that trials of any new therapeutic measure should be planned and carried out on an adequate scale. Otherwise the period of so-called trial may be extended far beyond the necessary limits; and a useless measure may be employed sporadically for years, or—what is far more serious—a useful

measure may fail to obtain general recognition because the reports on inadequate trials are contradictory and confusing. Any student who cares to master the history of the use of anti-pneumococcal serum (see pp. 1675-1679) will find a case in point.

It should be noted that, in the case of a proposed method of prophylaxis, our field trials will often have to be carried out on a far larger scale, because the risk of contracting a particular infective disease is often far smaller than the risk of dying from it when contracted. If the attack rate of a disease is very low, our immunized and non-immunized groups must be greatly expanded—often to many thousands of persons—before the number of cases in our control group will be large enough for us to establish the significance of any difference in morbidity that may be noted.

If, however, we can select special groups that are for some reason exposed to a particularly high risk of infection—such for instance as the nurses or attendants in a fever hospital—we may be able to detect the effect of a given prophylactic method by the immunization of relatively small groups (see p. 1474). The same will hold, of course, for the population at large in the case of infections with a very high attack rate, such as the common cold (see p. 1654).

We have so far been concerned with problems in which each animal, or each patient, gives a qualitative result—death or survival, infection or no infection. There is obviously another kind of problem in which each animal may give a quantitative result: it may live so many days, or lose so much weight, or its temperature may rise so many degrees, and so on. We deal with a problem of this kind by a method that is essentially similar to that described above. We have, say, a number of values for the time to death in each group, and from these two distributions of values we calculate the mean time to death and the standard deviation of the distribution. We compare the two means as before by finding the difference between them, and finding the value of the difference in terms of its standard error. As before, we need the standard error of each mean. The general expression for this quantity is

$$\text{Standard error (S.E.) of Mean} = \text{S.D.}/\sqrt{N}$$

where S.D. is the standard deviation, and N the number of observations. In the particular case, N is the number of measurements of mean time to death. (The formula $\sqrt{p_1q_1/n_1}$, employed on p. 987 for the standard error of the mean was valid only for a simple binomial distribution when $N = 1$.)

The ratio of the difference to its standard error gives us the value we need in order to obtain, from Table 60, the odds against the observed difference having been due to chance.

To take a concrete example, omitting the necessary calculations.

A group of 30 mice that had received certain immunizing injections, and 30 untreated mice as a control, were injected intraperitoneally with 1,000 *Salm. typhi-murium*. During the subsequent month 25 of the immunized mice died, and 28 of the controls. This was a trivial difference. But the mean time to death of the 25 immunized mice was 10·52 days with a standard error of 0·960 days, while the mean time to death of the 28 control mice was 5·93 days with a standard error of 0·924 days. The difference is 4·59 days, and the standard error of the difference is $\sqrt{0{\cdot}960^2 + 0{\cdot}924^2} = 1{\cdot}33$. The ratio of the difference to its standard error is $4{\cdot}59/1{\cdot}33 = 3{\cdot}45$, and the odds against observing such a difference as the result of chance (Table 60) are about 2,000 to 1. The conclusion is that we have almost certainly made the disease less acutely fatal as the result of an immunization, although we have not increased the resistance of our mice to the point at which their chance of survival is significantly increased.

THE MEASUREMENT, OR COMPARISON, OF TOXICITY OR VIRULENCE

We often want to determine the minimal lethal dose of a bacterial toxin, or of a living bacterial culture. Still more often we want to compare the minimal lethal dose of two toxins, or of two cultures. Clearly we must first titrate graded doses of the two cultures against a number of groups of animals. The results of such titrations are instructive. If we divide a large number of similar animals into groups of equal size, and administer to each group one of a series of increasing doses of a lethal culture or toxin, we may observe, if the scale of doses was suitably chosen, that none of the animals dies in the group receiving the smallest dose. With each increase of dose a larger death rate is observed and in the group receiving the largest dose all the animals die.

TABLE 63

13	100	1

Table 63 shows a set of hypothetical percentage mortalities in 12 groups of 100 animals, each group being given one of a series of doses of a lethal toxin. Each dose differs by one unit of measure from the preceding dose. If we plot death rate against dose, as in Fig. 239(A), we obtain a *characteristic* curve (Trevan 1927, 1929, 1930) for the toxin, or, more specifically, a dose-response curve. The third column of Table 63 records the values obtained by subtracting from the mortality rate for a given dose of a units, the mortality for the preceding dose, $(a - 1)$ units. Inspection both of column 3 and Fig. 239(A) reveals one of the most important features of the dose-response curve, namely that the rate of change of percentage mortality is greatest in the middle range of the curve. At the extremes, a relatively large change in dose results in a small change in mortality. That is, for a certain grading of doses, we shall be able to determine doses that kill 50 per cent. of a group of animals with much greater accuracy than those that kill 100 per cent. Trevan introduced a convenient notation for these various doses. The 50 per cent. killing dose is symbolized by LD50, where LD = lethal dose; the 100 per cent. killing dose by LD100, and so forth. If, as in Fig. 239(B), the dose-response curve is steep, the inaccuracy of finding the exact LD100 is clearly less than in (A). In the past, with toxins like that of *C. diphtheriæ*, which have a steep dose-response curve, the LD100 has successfully been used as a measure

of toxicity. It corresponds, in fact, to the minimal lethal dose (p. 238). With other toxins, and with cultures of pathogenic bacteria, the dose-response curve is far less steep. In Table 65, for example, the dose of the Ellinger strain of bacteria increases by 100-fold at each step, yet the rate of change of percentage mortality is relatively small, especially as the LD100 is approached. The LD50 can be more

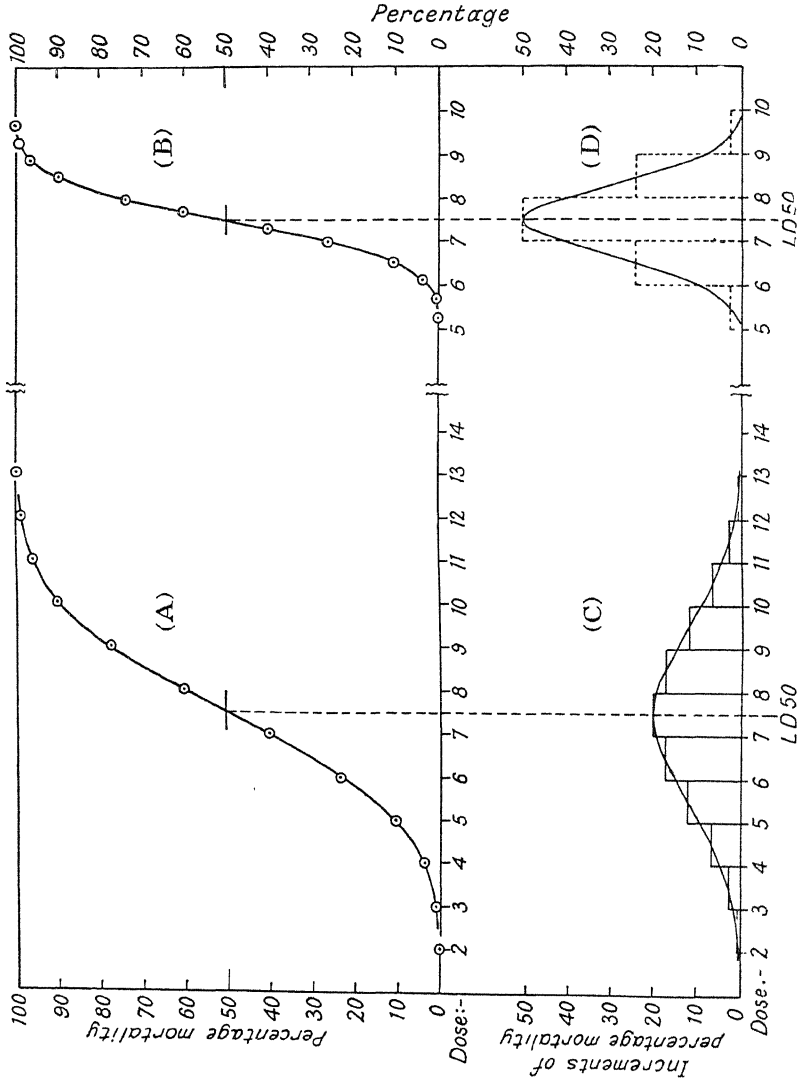

Fig. 239.

accurately measured, and even with steep dose-response curves, it is to be preferred to the LD100. In essentials, then, toxicity or virulence is best measured in terms of the LD50.

It is instructive to inquire why the dose-response curve has this particular S-shape. If we assume that each group of 100 animals is representative of the total of 1,200 animals

from which they were drawn, it is clear that the figures in column 3 of Table 63 represent the proportion of all the animals which are susceptible to a dose of a units, but not to a dose of $(a - 1)$ units. In each case, then, we may say that the recorded proportion of animals is on the average susceptible to a dose half-way between these two values, that is, $(a - 0{\cdot}5)$ units. Thus, the 3 per cent. of the animals susceptible to 4 units but not to 3 units, are on the average susceptible to 3 5 units, and so forth. Plotting these proportions against doses as abscissæ we obtain the curve in Fig. 239 (C), which is in effect a frequency distribution of susceptibilities in the population of animals employed. The average, or mean resistance, corresponds to the LD50. The hypothetical curve B represents the response of another batch of animals to the toxin, estimated from a series of doses increasing by 0·4 units. The curve (D), the distribution of susceptibilities derived from it, has been drawn on a scale of unit increases in dose, for comparison with the curve (C). It is clear that the steeper dose-response curve corresponds to a narrow distribution of susceptibilities obtained in the performance of the test. These distributions. it should be noted, are distinct from the distributions of chance effects discussed on p. 983, which were derived from an ideal population of identical animals infected with a fixed dose. Here we are estimating how widely the population of animals varies in resistance to graded doses, though each mortality measurement is subject to the error discussed above. In estimating the mortalities from which the dose-response curve is built, we shall have to take into account both sources of error—the error due to heterogeneity of the animal population tested, and the error due to chance effects in small groups of animals. If the death-rate of a group is known, the last can be estimated by the $\sqrt{npq}$ formula; the first, only by measuring the slope of the dose-response curve.

It will be clear that the more homogeneous the animals used, the more they approximate to an ideal test reagent and the smaller the error of measurement with a group of animals of a given size. Some breeds of laboratory animals used for biological assay of this kind are grossly heterogeneous, but it is possible to reduce the heterogeneity by inbreeding of selected strains. These inbred strains, which may or may not be pure lines, often yield much steeper dose-response curves than those of the parent strains, and their use in biological assay permits either a greater increase in the accuracy of an assay for the expenditure of the same number of animals, or measurements of the same accuracy with smaller numbers of animals. For example, Prigge (1937) records that the ratio of the smallest to the largest dose of diphtheria toxoid required to immunize the individual animals in a mixed laboratory strain of guinea-pigs against a standard injection of toxin was 1 : 32,000. Similar tests of pure line strains inbred by brother-sister matings revealed a strain for which the ratio was as small as 1 : 25.

The LD50 may be estimated directly from a dose-response curve. One simple method is to fit a straight line to observed mortalities whose values lie between 25 per cent. and 75 per cent. and read off the LD50. Its accuracy depends on the assumption that the curve is approximately a straight line between these limits. It is limited in that observed mortalities greater than 75 per cent. and less than 25 per cent. have no weight in determining the final answer. Accurate and relatively simple methods of estimating the LD50 from *all* the observed mortalities are available. The technical and mathematical considerations (of which we have discussed only very limited aspects) involved in assessing the significance of the necessary *in vivo* titrations are beyond the scope of this book. Those who desire further information should consult the papers by Gaddum (1933), Irwin (1937), Bliss (1938), and Prigge and Schäfer (1939). Reed and Muench (1938) and Irwin and Cheeseman (1939*a*, *b*) have developed simple arithmetical methods for use with small-scale laboratory data.

As we have noted above, the killing power of exotoxins and other non-living substances is assayed with comparative ease. Two concrete examples will serve to illustrate the difficulties with which we are faced when we endeavour to determine the average lethal dose of a bacterial culture, or to compare the virulence of two bacterial strains.

A series of six dilutions were prepared from a culture of pneumococcus of moderate

virulence, and the same amount of each dilution was inoculated into 40 mice. The doses administered, in terms of living pneumococci, were 10^6, 10^5, 10^4, 10^3, 10^2 and 10. Two of the mice that received each dose were then allotted at random to each of 20 numbered groups. Each group thus consisted of 12 mice, 2 for each dose tested. The deaths are recorded in Table 64.

TABLE 64

SHOWING THE NUMBER OF DEATHS IN 20 SAMPLES, EACH OF 12 MICE, INOCULATED WITH THE SAME SERIES OF GRADED DOSES OF THE SAME CULTURE OF PNEUMOCOCCUS.

Dose	Group.																			
	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20
10^6	2	2	2	2	2	2	2	2	2	2	2	2	2	2	2	2	2	2	2	2
10^5	2	2	2	2	2	2	2	2	2	2	2	2	2	2	2	2	2	1	2	2
10^4	1	2	1	1	2	1	2	1	1	2	2	2	1	2	1	0	1	0	2	1
10^3	1	0	0	0	0	1	0	0	0	1	1	0	0	0	0	0	0	0	0	0
10^2	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0
10	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0

Adding across the rows, the percentage mortality for the whole series was, with the falling doses, 100, 97·5, 65·0, 10·0, 0 and 0. The average lethal dose was probably something between 10,000 and 1,000 pneumococci. But if we had used two mice for each dose—and it would have been a highly conventional procedure—we should have said in the case of groups 10 and 11 that the average lethal dose was about 1,000 pneumococci; in the case of groups 1, 2, 5, 6, 7, 12, 14 and 19 that it lay somewhere between 1,000 and 10,000 pneumococci; in the case of groups 3, 4, 8, 9, 13, 15, 16, 17 and 20 that it was about 10,000 pneumococci; and in the case of group 18 that it was about 100,000 pneumococci. Had we been comparing 20 different strains of pneumococci, we might have been unwise enough to hazard the statement that strains 10 and 11 were about 100 times more virulent than strain 18; whereas, as this experiment showed, there would have been no adequate reason to assume any difference in virulence.

As an illustration of the comparison of the virulence of two different strains of a given bacterium we may take the data recorded by Lockhart (1926) in regard to the mortality produced by different doses of two strains of *Salm. typhi-murium*, "Ellinger" and "A52," all injections being given intraperitoneally. The figures are set out in Table 65.

TABLE 65

Dose.	Number of Mice in Each Group.	Mortality per cent. Strain A52.	Mortality per cent. Strain Ellinger.
10,000,000	25	92	96
100,000	25	48	88
1,000	25	44	56
10	25	16	24

We can feel fairly confident that the Ellinger strain is more virulent than the A52 strain; at each dose level it has given a higher mortality. But we clearly cannot express our result as any numerical ratio. If this is the best we can do with 200 mice, we must be satisfied to detect gross differences in virulence, so far as this organism is concerned.

THE STANDARDIZATION OF IMMUNOLOGICAL PRODUCTS

It may be noted here that the method of direct comparison is always employed when we wish to standardize an immunological reagent, *i.e.* to express its value in terms of some arbitrary unit. Thus if we wish to standardize an anti-diphtheria serum in terms of units of antitoxin, we compare its protective value with that of a particular antitoxic serum which is accepted by international agreement as the standard of reference. This standard serum has been submitted to very careful assay and has been allotted an agreed but arbitrary value in terms of antitoxin units. Once this value has been allotted it remains the permanent standard for the antitoxin, or other reagent, in question.

The statistical considerations involved in these comparative neutralization tests are of the same kind as those involved in comparisons of toxicity or of virulence; but the size of the sampling errors, and hence the accuracy of our titrations, are modified by the actual procedure adopted in each particular case. Here again reference may be made to papers quoted in the preceding section.

A NOTE ON THE RECORDING OF QUANTITATIVE RESULTS

It is a common habit among immunological workers to record their quantitative results in the form of curves or charts. The advantage is obvious. The meaning leaps to the eye. The danger is that it sometimes leaps before one looks It is a very safe rule never to trust the tale told by a curve until the quantitative data on which it is based have been critically examined. If the points through which a curve is drawn are based on figures which are subject to errors of random sampling, and if the data permit the standard deviation to be calculated, it is a good plan to mark off three times the standard deviation above and below each point on the curve, join up these points, and, realizing that the curve might run anywhere within the broad band thus demarcated, reconsider its actual significance.

Tables are duller things than curves, and rather more trouble to master. But they tell much more illuminating tales. They should always state quite plainly the number of observations made, never percentages without this information. If a table has a column headed " per cent." always look first at the columns giving the figures on which the percentages are based. Occasionally it will be found that 33·33 per cent. in the last column corresponds to a 1 and a 3 in the columns preceding it. In such cases, of course, the 33·33 per cent. is quite meaningless.

THE VALUE OF QUANTITATIVE MEASURES OF ERROR

The quantitative results of biological tests or observations can be used with confidence only if the error to which the estimation is subject is known with sufficient accuracy. Statistical analysis of the experimental data may reveal both the errors due to the variability of the material used, and the errors inherent in the technique of experiment; and with a measure of the total error we may assess the statistical significance of any numerical result. Without such an estimate of error, we can compare neither two experiments by one worker, nor the experiments of several workers. It is not, however, enough to submit the finished data to statistical tests. Simple statistical principles of the kind we have been considering are not rules to be applied in drawing conclusions from an experi-

ment that has been done—*they are part of the experiment itself, an essential factor in its proper planning.*

The statistical method does not consist merely in applying arithmetical analysis to the numerical results of an experiment. It includes the detection and elimination of bias, and the proper appreciation of the variables to be considered, both in the design and technique of the experiment, and in its analysis. It is often possible, for example, by a simple consideration of the numbers of animals available for a given test, to say that the experiment is unlikely to give a significant answer. In such a case, the test is much better made upon a larger scale, or abandoned altogether.

A word of warning is needed. No conviction of the necessity for the proper design of experiments, and for the statistical analysis of the results obtained, should lead us to over-estimate the support that a statistically significant result can give to the particular hypothesis the experiment was intended to test. As Fisher (1942) points out, all that a properly designed experiment can test is the "null hypothesis"; that is, the hypothesis that there is no difference between the control and test systems that we are studying. If, for example, the calculated odds prove to be 3 to 1 against a chance effect in the defined conditions of a therapeutic test of a fluid A in a fatal bacterial infection, no one could decide, without further experiment, whether the effect observed was due to "chance" or to A. If the odds prove to be 1,000 to 1, we can say that the effect is unlikely to be an example of a chance variation of the kind we expect from the materials used in the test; but we cannot say that it was *therefore* due to the administration of a few millilitres of the fluid A. The statistically significant result indicates that the test and control groups differ in some important respect and therefore permits us to consider the fluid A as a possible cause of that difference; but the decision that A *is* the cause of the observed reduction in mortality in the test group is independent of any statistical demonstration of significance and in a final analysis depends on the experimenter's knowledge of his particular science and his appreciation of the consistency of his ideas of A's action with the general theory of that science. If A was in fact water, the conclusion, no matter how statistically significant the experimental result, that a small quantity of water had cured the infection, would rightly be considered as suspect. If A, on the other hand, was a solution of a substance known to be antibacterial and non-toxic to the animals used in the experiment, then these pieces of scientific knowledge, coupled with the disproof of the null hypothesis, would go far towards justifying the conclusion that A was capable of curing a particular type of infection.

The aim, then, of the statistical method in experiments involving the comparison of two or more groups of events is to discover how far the null hypothesis is likely to be true; and only in those cases where the null hypothesis is disproved is there any justification for considering the possibility that an observed effect resulted from any of the deliberate variations in the conditions of the experiment.

The proper design and analysis of quantitative tests is essential for the efficient practice of a science. That the record of immunological work in the past contains few examples of statistical analysis is no proof that such analysis is unnecessary. Sometimes the results of an experiment are so clear cut that any arithmetical analysis is unnecessary; on many other occasions it will be found that the data are incapable of supporting the conclusions reached by the investigators. There is no doubt that much of value has been learned without any consideration of

statistical design, but it is justifiable to suppose that the knowledge could often have been achieved with a great deal less expenditure of time and materials had the experiments been designed more efficiently.

The voyager who ignores tidal streams and compass deviations will arrive somewhere in the long run; but he is less likely to identify correctly the place at which he has arrived than is another who allows for these variables by the accepted methods of elementary navigation.

CHAPTER 44

THE MECHANISMS OF BACTERIAL INFECTION

BEFORE we can discuss the mechanisms by which the host resists infection, we need as clear a picture as possible of the ways in which the parasite injures the host. Some parts of the picture are confused, others sketchy; but parts of the main outline are quite clear and definite, and it is with these that we shall be mainly concerned.

Specific Infection. Koch's Postulates.

Although not immediately pertinent to our main problem, a brief discussion of the kind of evidence which will justify the conclusion that a particular disease is caused by a particular parasite forms a convenient introduction to the consideration of infective processes in general, and raises points of some interest and importance.

A series of conditions, which must be fulfilled in order to establish such a causal relationship, are set out in most bacteriological textbooks under the title of "Koch's Postulates," though there is no clear evidence that Koch ever enunciated them in the categorical form in which they are usually quoted. They run in general terms as follows:

(1) The organism should be found in all cases of the disease in question, and its distribution in the body should be in accordance with the lesions observed.

(2) The organism should be cultivated outside the body of the host, in pure culture, for several generations.

(3) The organism so isolated should reproduce the disease in other susceptible animals.

We should to-day recognize additional ancillary criteria which help us to form an accurate judgment as to the relationship of a suspected organism to a given disease, as, for instance, the demonstration of specific antibodies in abnormally large amounts in the blood of an infected man or animal, or an abnormally high degree of specific immunity to the infecting agent in a recently recovered animal.

It is obvious that technical difficulties may prevent us from fulfilling all Koch's postulates in every case. We may, for instance, be unable to cultivate the causative parasite although we can demonstrate its constant presence in the lesions by suitable staining methods; this has hitherto been the case with regard to the bacillus of leprosy. Or the organism may be so small, and its morphology so doubtful, that we are unable to demonstrate its presence in the tissues, or to differentiate it with certainty from other bodies of the same order of size. If, to this difficulty, is added an inability to cultivate the organism *in vitro*, we may, as in the initial studies on most virus infections, be compelled to take a short cut, neglect the first two postulates, and rely on the reproduction of the disease in a suitable animal by the inoculation of filtrates from infected blood or tissue extracts,

which are at least free from intact cells or living bacteria. In other cases the third postulate may be our stumbling-block. We may be able to demonstrate a characteristic bacterium in such a relation to the lesions of a particular disease that we can have no reasonable doubt that it is playing a causative rôle, and we may have learned how to propagate it in pure culture outside the body; but we may be quite unable to produce in any experimental animal lesions which bear any close resemblance to those which characterize the disease in man.

It is often possible, in the absence of complete proof, to establish the causative rôle of a particular organism with so high a degree of probability that there need be no hesitation in accepting this association as a reasonable provisional hypothesis. At the same time it must be recognized that any omission in the complete chain of evidence involves a risk of error; and much confusion has been caused by uncritical attempts to support the claims advanced on behalf of numberless bacteria isolated from different parts of the body in various diseases.

A little more may usefully be said with regard to the first and third postulates. In the early days of bacteriology the proposition that the causative organism of a disease should be present in every case adequately examined was held to imply its converse—that the organism should not be present in persons not suffering from the disease. And in some instances, such as the investigations that followed Loeffler's demonstration of the diphtheria bacillus, serious doubts were thrown on the claim of an authentic causal organism when it became clear that it could be isolated from the throats of persons who were quite certainly not suffering from diphtheria. Nowadays our conception of the probable distribution of any pathogenic parasite is that it will be found in every case of the specific infection that is clinically obvious and is adequately investigated under satisfactory conditions; in many cases of minor infection that show little resemblance to the fully developed disease; and in a certain proportion of apparently healthy persons, especially in contacts.

With regard to the third postulate, we should not expect complete identity between the clinical picture in man and the lesions produced in an experimental animal. The picture presented by any infective process depends as much upon the reactions of the host's tissues as upon the activities of the infecting parasite; and in this, as in other respects, one animal species differs from another. Sometimes this is a small matter. No one who had any knowledge of the morbid anatomy of tuberculosis in man or cattle would hesitate in identifying the experimental disease in the rabbit or guinea-pig, in spite of minor superficial differences. But the lesions produced in experimental animals by the typhoid bacillus, or by the scarlatinal streptococcus, bear little obvious resemblance to the corresponding human diseases.

The student should note very carefully that there are two distinct stages in the use of experimental animals in the study of infective disease. In the first we are trying to reproduce a particular infection in a form which is clinically or pathologically recognizable as identical with the natural disease. This is the kind of reproduction demanded by Koch's third postulate. In the second we are utilizing our susceptible animal for an intensive study of the particular infective process with which we are concerned. This is really the more significant and interesting part of our investigations. The lesions produced in the guinea-pig by the subcutaneous inoculation of cultures or filtrates of the diphtheria bacillus bear little resemblance to diphtheria as it appears in man; but almost the whole of our present knowledge of immunity in relation to that disease, which has at last placed us in a position to exert effective control, has been built up on knowledge gained from experiments on that small laboratory animal.

It should be noted, also, that there is a shifting of emphasis from the clinical to the bacteriological side as our knowledge progresses. At the start of our inquiry

we are presented with a clinical or epidemiological phenomenon, and our task is to discover the microbial parasite that is the necessary cause. We may, as in the case of diphtheria, or syphilis, or tetanus, find that a single specific parasite is responsible; indeed this is far the most frequent solution if we neglect racial variations within the causative microbial species. We may, however, find that a disease characterized by one clinical syndrome may be caused by one of several distinct species of bacteria. Secondary pneumonia affords one example, bacillary dysentery another. Once the connection between a particular parasite and a particular disease has been firmly established, the tendency of the bacteriologist is to focus his attention on the organism, rather than on the clinical condition to which it most frequently gives rise, and to try to build up a picture of the reactions between that organism and a susceptible host species in general. Thus we should think in terms of pneumococcal infection, rather than in terms of pneumonia; and regard that particular condition merely as one example of the reaction between the pneumococcus and the human tissues, including in our generalized picture such lesions as middle-ear disease, sinusitis, meningitis, peritonitis, suppurative arthritis, etc., and keeping constantly in mind the part played by bacteræmic spread and selective localization.

It will be convenient, in this and the immediately succeeding chapters, to deal exclusively with bacterial infections, since most of our knowledge has been acquired in studying infections of this type. In a later chapter we shall discuss how far our conceptions have to be modified in the case of infections with the filtrable viruses. Protozoal and helminthic infections are beyond the scope of this book; though the methods elaborated by the bacteriologist are proving fruitful in their application to this wider field.

Invasion of the Tissues by Bacteria.

With very few exceptions, bacteria and other microbial parasites must gain access to the host's tissues and multiply in them before they can produce any harmful effect; and we may for the moment regard the capacity to pass through some protective covering layer—most commonly through one of the mucous surfaces of the body—and to multiply in the subjacent tissues, as an essential attribute of a pathogenic organism. The " passing through " must not, of course, be interpreted too literally, or as necessarily implying any active motion on the part of the parasite. Apart from gross mechanical injuries to the skin and mucous membranes, the routes by which micro-organisms and inert particles of non-living matter get into the tissues are probably the same. The skin and mucous membranes of the mammalian body are liberally supplied with lymphatic channels, and access through these channels appears to be particularly easy in those areas where they are near the surface, as in the nasopharyngeal region, the tonsils, and the lymphoid follicles of the intestine. In other cases bacteria may reach the crypts of mucous glands, and then, after local multiplication, penetrate to the subepithelial tissue. In any event it is probable that the capacity for invasion depends in considerable part on a capacity to withstand the conditions existing on the particular surface where lodgment is first made, or in the channels or viscera through which the parasite must pass before it gains contact with a penetrable surface. Little is known of the first stage of infection, the transit of the infecting agent from the outside world to the host's tissues, and the significance of much of it is not always obvious. It will be more convenient to deal with this aspect of the question

in a separate chapter, and to pass at once to the events which follow the passage of the parasite into the tissues.

A broad distinction can be made between those parasites which tend to remain localized at or about their point of entry, and those which are rapidly disseminated throughout the body and produce a generalized infection associated with a bacteræmia. It is unlikely, as we shall see later, that any bacterial parasite multiplies freely in the blood stream, and the presence of large numbers of bacteria in the circulating blood would seem, in most cases, to be the expression of a loss of equilibrium; either a rapid overflow of organisms from extravascular foci of infection overwhelms the clearing mechanisms of the blood, or the clearing mechanisms are themselves put out of action.

The property of invasiveness is one of the characters which distinguish one bacterial species from another, or one strain from another within the same species. Since, in many cases, the pathogenicity of a particular bacterial parasite appears to be mainly determined by its relative rapidity of spread within the tissues, it is logical enough to refer to those species which spread rapidly as *virulent* and to those which spread slowly, or not at all, as *avirulent*; and this usage is generally followed. The term *virulent* is sometimes used as though it were completely synonymous with *invasive*; but this usage is unjustified by derivation and singularly inconvenient in practice. If rigidly adhered to it would necessitate the exclusion from the class of virulent bacteria of all those organisms that exert their lethal effect by the production, in localized foci, of powerful toxins. We could, for instance, no longer speak of virulent and avirulent diphtheria bacilli. It is better practice to retain the term *virulent* in its correct sense of *poisonous*, without any implication as to how the poisonous effect is produced, and to apply it to any organism which gives rise to a rapidly fatal infection. The particular attributes on which virulence depends can be described in other terms.

It may, then, be stated that multiplication of bacterial cells within the tissues is one of the essential factors on which infection depends. Some species can produce a fatal infection without any wide dissemination within the body, others cause death only when such widespread dissemination occurs. A part of the mechanism of resistance will clearly be concerned with the killing and removal of the bacterial cells as such.

Bacterial Localization.

Apart from the generalized bacteræmic invasion referred to above, most bacteria tend to lodge and multiply in tissues remote from their point of entry to the body; and certain species, or groups of species, differ sharply from one another in regard to the particular tissues or organs in which such localization occurs.

The site of the primary lesion and the direction of the initial spread of infection are largely determined by the portal of entry to the body, and by the local anatomy, particularly by the direction of the lymph flow. But the portal of entry in its turn is determined by the natural habitat of the parasite, and this by its potentialities for life under different environmental conditions.

Thus, some types of staphylococci are normal inhabitants of the skin. Those types, or races, that are potentially pathogenic, may gain access to the underlying tissues by the hair follicles, or by the ducts of the sebaceous glands, and cause the characteristic pustules or boils.

Many of those bacteria that lead a parasitic existence in the nasopharynx, and are spread from host to host by droplet infection, tend in consequence of this common portal of entry to show a rough similarity in the distribution of the lesions they

produce; but the similarity is very incomplete, and breaks down altogether on a close analysis. Thus, pneumococci, hæmolytic streptococci, influenza bacilli, diphtheria bacilli and meningococci are all spread by droplet infection. Diphtheria bacilli and hæmolytic streptococci both tend to lodge and multiply in the tonsils, the former giving rise to the characteristic lesions of faucial diphtheria, the latter to tonsillitis. Both produce soluble toxins, which diffuse widely from the initial lesion. But the tendency to invasive spread is much greater in the case of the streptococcus than in that of the diphtheria bacillus. Pneumococci, hæmolytic streptococci and influenza bacilli may all spread to the lungs and cause pneumonic lesions, but their rôle in this regard is very different. The pneumococcus fully merits its name by its pre-eminence as an invader of the pulmonary tissue. It is the sole important bacterial agent in the primary pneumonia of adolescence and adult life. In the secondary pneumonias associated with such infections as measles, whooping cough and influenza, it shares its honours with the influenza bacillus and the hæmolytic streptococcus. The meningococcus, although it is a nasopharyngeal parasite and spreads by droplet infection, produces its characteristic lesion in the meninges. Pneumococci, hæmolytic streptococci and influenza bacilli may also give rise to meningitis; but whereas this is the modal reaction of the meningococcus, when it produces clinically obvious infection, it is a relative rarity among the host of pathogenic reactions caused by the three other bacterial parasites.

The common sites of the primary lesions of syphilis are obviously determined by the venereal mode of infection; but the secondary and later stages are the same whether the primary chancre was genital or extragenital, and the tissues affected and the lesions produced are highly characteristic of the disease.

These instances serve to emphasize that the distribution of infective lesions depends in large part on the biological characters of the infecting parasite, and their relation to the various local metabolic processes in the different tissues of the part.

The intravenous injection of the bovine tubercle bacillus into rabbits, for example, produces visible lesions in the kidney, but none or few in the liver or spleen. Yet in the early stages of the infection, bacilli proliferate equally in all these organs (Lurie, 1928, 1929, 1933). In the guinea-pig, on the other hand, tubercles flourish in lung, liver and spleen. These variations in the susceptibility of organs have their counterpart in variations in the susceptibility of different classes of cells to infection. The studies of Goodpasture and his colleagues on the spread of experimental infection in the embryo of the chick have revealed striking differences in the mode of proliferation of different bacteria (see Goodpasture and Anderson 1937, Gallavan and Goodpasture 1937, Buddingh and Polk 1939, Buddingh and Womack 1941). The proliferation in the embryo of the diphtheria bacillus, the plague bacillus, *Staph. aureus.*, *Str. pyogenes*, the pneumococcus and *H. pertussis* is mainly extracellular; *Str. viridans* and the meningococcus multiply to some extent in the cytoplasm of certain living cells. *Br. tularensis* proliferates intracellularly, mainly in ectodermal cells, and the striking feature of invasion by *Br. suis* is its rapid proliferation in the mesodermal endothelium of the vessels.

The explanation of these variations in organ susceptibility is obscure, though in some cases it may apparently be simply referable to anatomical features. For example, the readiness with which joints are infected after intravenous injection of certain bacteria may be due, not to an inherent arthrotropism of the bacteria used, but simply to the small amount of tissue that separates the cavity of the joint from the rich capillary plexus below the synovial membrane (Shaffer and Bennett 1939). Buddingh (1944) on the other hand, working with a strain of *Streptobacillus moniliformis* isolated from a patient with rat-bite fever (see Chapter 57), found that the organism invaded the chick embryo,

rapidly producing a bacteræmia which was followed by an apparently selective localization in the cells of the synovial linings of the joints, and subsequent invasion of the joint cavity.

The Stimulation of Specific Cellular Reactions.

The differences between the infections produced by the various pathogenic micro-organisms are not confined to the distribution of lesions within the body. The lesions themselves are different and may be highly characteristic. The tendency of certain bacterial species to stimulate a localized polymorphonuclear reaction, associated with pus formation, has earned for them the title "pyogenic." Such experimental evidence as is available indicates that the migration of polymorphonuclear leucocytes to the focus of infection is the direct result of an attractive (chemotactic) effect, exerted by some diffusible bacterial product. Equally characteristic lesions, which differ among themselves, are produced by the various non-pyogenic organisms. The diphtheria bacillus, the typhoid bacillus and the *Treponema pallidum* give rise to tissue reactions which are so distinct that any competent histologist could differentiate them without bacteriological assistance. The special case of tuberculosis is of particular interest, in that a beginning has been made in tracing the connection between the various chemical products of the bacterial cell and the type of tissue reactions to which they give rise (see p. 410).

It is not, of course, the case that every pathogenic bacterium provokes a distinct and characteristic cellular response, or that the pathologist unaided can often arrive at an exact bacteriological diagnosis from a histological examination of the infected tissue ; but, as Kettle (1927) has pointed out so clearly, there is a broad correlation between certain types of lesion and certain groups of bacteria, and the groups which the pathologist would recognize on the basis of the distribution and type of the lesions produced are, in many cases at least, those which the bacteriologist would recognize as containing closely related bacterial species.

All this may seem very obvious and elementary ; but it is of the first importance to realize that different pathogenic parasites have different points of attack, and different methods of attacking.

Bacterial Toxins.

There is no apparent reason why the mere presence in the tissues, or blood stream, of any reasonable number of cells of an order of size expressed in low multiples of μ should exert any harmful effect on the host that harbours them. No mechanical theory of the pathogenic action of bacteria is compatible with our knowledge of the way in which the tissues deal with inert particles which have gained access to them. The basis of all harmful effects of bacterial infection is quite certainly chemical ; and only when the chemist has replaced the immunologist shall we be able to give an intellectually satisfying account of what happens when a particular parasite invades a particular host. In the meantime we must do what we can with the crude data at our disposal.

It has long been known that certain bacterial species produce highly poisonous substances which give rise to characteristic lesions or symptoms when injected into susceptible animals. These are the bacterial toxins. A convention has become established according to which those toxins which diffuse readily from the bacteria that produce them are referred to as *exotoxins*, while poisonous substances which remain attached to the protoplasm of the bacterial cells are referred to as *endotoxins*. As knowledge has accumulated, it has been possible to correlate this character with

others, and a broad distinction may be made between characteristic members of the two groups.

A typical exotoxin is readily separated from a bacterial culture, in a suitable fluid medium, by simple filtration through a candle of porcelain or diatomaceous earth. It shows a characteristic affinity for certain cells of a susceptible host, producing easily recognizable symptoms during life, or lesions which can be detected after death. Thus one exotoxin can usually be distinguished from another by what we may term its pharmacological action. Instances of this specific effect are afforded by the action of tetanus toxin on the motor nerve cells, by the ocular and pharyngeal paralyses caused by the toxin of *Cl. botulinum*, and by the cardiovascular failure, the hæmorrhagic lesions of the adrenals, and the late paralysis in animals that survive, which are a characteristic of experimental diphtheritic toxæmia.

An exotoxin is usually fatal in a very small dose. The *Minimal Lethal Dose* of a potent diphtheria toxin for a guinea-pig is about 0·002 ml., of a potent tetanus toxin about 0·0005 ml., and of a potent botulinum toxin about 0·0001 ml. Such toxins are usually relatively thermolabile. Diphtheria toxin is inactivated by heating at 58°–60° C. for 1–2 hours; tetanus toxin by heating at 60° C. for 20 minutes. Lastly—and this is a matter which will be considered more fully in a subsequent chapter—exotoxins are usually highly antitoxinogenic; that is, on inoculation into a suitable animal they stimulate the production of antitoxins which neutralize them specifically; and broadly speaking the amount of antitoxin needed for neutralization is directly proportional to the amount of toxin present.

The typical endotoxin is not liberated into the fluid medium in which the bacterium producing it is growing, and hence cannot be separated from the bacterial cells by simple filtration. It is liberated in solution or suspension by various treatments of the cell, alternate freezing and thawing, prolonged grinding, subjection to sonic vibration, extraction with different solvents—or by merely allowing cells to autolyse in a fluid medium. Toxins of this type may in most cases be demonstrated by the injection into a susceptible animal of the unaltered bacterial cells. In this case it is assumed that the liberation of the toxin is brought about by the lysis of the cells *in vivo*. The endotoxins do not, in general, give rise to diagnostic symptoms or lesions in experimental animals, so that it is not usually possible to recognize any particular endotoxin by its pharmacological action. The *Minimal Lethal Dose* of a typical crude endotoxin is in general larger than that of a typical exotoxin; sometimes the ratio is of the order of 1,000,000 to 1. Thus the M.L.D. of a killed broth culture of the cholera vibrio is about 0·5 ml. for the guinea-pig, the M.L.D. of meningococcus for the mouse is about 2 mgm. of bacillary substance, and the M.L.D. of the gonococcus for the same animal is about 10 mgm. of bacillary substance. Endotoxins are usually relatively thermostable. Cholera endotoxin requires 1 hour's heating at 80°–100° C. for its inactivation; the endotoxin of the meningococcus requires 1 hour's heating at 120° C.; while the same treatment has failed to inactivate the endotoxin of the gonococcus. The virulent S form of *Sh. shigæ* produces two main toxic components which will illustrate the differences between "exotoxins" and "endotoxins." The "exotoxin" has a mouse M.L.D. of $< 0{\cdot}001$ mgm., is an actively antigenic thermolabile protein, and induces characteristic paralyses in mice and rabbits. The "endotoxin" has a mouse M.L.D. of about 0·1 mgm., is a thermostable moderately antigenic complex of phospholipin, polysaccharide and conjugated protein, and, though its capacity to produce marked œdema and hæmorrhages in the gut of experimental animals has earned for it the name of "enterotoxin," it does not differ qualitatively in its general toxic action from similar components in other intestinal bacilli.

The endotoxin of a number of other Gram-negative intestinal bacilli, tested in more or less pure preparations, have M.L.D. that vary round 0·1 to 1·0 mgm.

Finally, endotoxins are seldom strongly antitoxinogenic. In some cases it has proved impossible to prepare anti-endotoxic sera. More commonly prolonged immunization

of an animal yields an antiserum which is able to neutralize a few M.L.D. of the endotoxin; but the simple linear relationship between the amount of toxin and antitoxin in a just neutralized mixture, that obtains with exotoxins, does not hold with endotoxins. In many cases no increase in antitoxin affords protection when the dose of endotoxin passes a certain limit.

Although this broad distinction can be made by comparing typical exotoxins with typical endotoxins, not all toxins fall simply into two well-defined groups. Thus, the toxin of *Cl. botulinum* is a typical exotoxin, filtrable, with a very small M.L.D., with a characteristic pharmacological action, and antitoxinogenic; but it is relatively heat-resistant (75°–80° C. for 10 mins.). The α-toxin of *Cl. welchii* is filtrable, has a characteristic local action on the tissues, and is antitoxinogenic; but its M.L.D. is relatively large (0·02–0·1 ml. for the pigeon), and it is relatively heat-resistant (70° C. for 30 mins.). The erythema-producing toxin of the hæmolytic streptococcus—the toxin which is responsible for the rash in scarlet fever, and is employed in the Dick reaction—is filtrable, has a characteristic action on the skin of a susceptible person, and is antitoxinogenic; but its M.L.D. is very large (5–10 ml. or more of an unconcentrated filtrate for the rabbit) and it is very resistant to heat (96° C. for 45 mins.). The hæmolytic streptococcus also produces another filtrable toxic constituent which differs from the Dick toxin in being thermolabile (55° C. for 30 mins.), in causing lysis of red blood cells, and perhaps of leucocytes, though the identity of streptococcal hæmolysin and leucocidin is not accepted by all observers. Its M.L.D. is large, of about the same order as the thermostable toxin, but in this dose it kills susceptible rabbits within 24–36 hours with an associated hæmoglobinuria and characteristic evidence of intravascular hæmolysis at necropsy (M'Leod and M'Nee 1913, Channon and M'Leod 1929).

One implication which has sometimes—though without justification—been attached to the term "exotoxin" is very probably misleading. Toxins of this type have been described in words which suggest that they are of the nature of active secretions of the bacterial cells. There is little definite evidence that this is so. Though some exotoxins, as that of *Cl. welchii*, are produced in high concentration during the phase of active bacterial growth, others, such as diphtheria, tetanus and Shiga toxins, only attain a high concentration in a fluid culture when the phase of active growth has passed, and the majority of the bacteria present are dead or dying. How far autolytic processes may be concerned in toxin production is quite uncertain. Morton and Gonzalez (1942) compared the amount of toxin in the fluid part of a culture of diphtheria bacilli with that in the cells after disruption by sonic vibrations. Their results indicate a very much higher concentration of toxin in the cells, though the absolute amount of toxin in the fluid was the greater.

Most of the studies on bacterial toxins have been made with crude reagents—filtrates, autolysates or extracts of fluid cultures,—which quite certainly contain many substances other than the toxins. Moreover, it is now clear that a single species of bacterium may elaborate a number of different exotoxins and endotoxins. For instance, filtrates of *Cl. welchii* Type B may contain at least five distinct exotoxins; and two major endotoxins have been isolated from virulent typhoid bacilli.

Constitution of Toxins.—Few of the exotoxins have been characterized chemically. The toxin of the diphtheria bacillus is a heat-coagulable protein, very sensitive to denaturation (Eaton 1937, Pappenheimer 1937, Boivin 1937). Pappenheimer (1938) obtained some evidence that the integrity of the ε-amino groups of the lysine residues in diphtheria toxin was associated with its toxic properties.

Scarlet fever toxin appears to be a protein of low molecular weight (Barron, Dick and Lyman 1941), and both the exotoxin of *Sh. shigæ* (Boivin and Mesrobeanu 1937*a*, *b*) and the O hæmolysin of *Str. pyogenes* have the characters of a protein (Herbert and Todd 1941). A number of endotoxins, on the other hand, have been characterized with some precision. In both the salmonellæ and the dysentery bacilli, the antigens characterizing the smooth virulent phases are also the endotoxins. Boivin and his colleagues (1933–5) and Raistrick and Topley (1931) (see also Delafield 1934, Martin 1934, Boivin 1938) isolated from salmonella bacilli antigenic endotoxins which appeared to be complexes of a polysaccharide and a phospholipin. These glycolipoid complexes were split on mild hydrolysis into a non-toxic polysaccharide, and a feebly toxic lipin. Morgan (1937) isolated a similar substance from *Sh. shigæ*. Morgan and Partridge (1940, 1941) subsequently demonstrated a third component in the complete endotoxin of Shiga's bacillus, a polypeptide which appeared to be a conjugated protein. A similar polypeptide component is also present in the endotoxin of *Salm. typhi* (Freeman and Anderson 1941) which proved to be identical in all respects tested with the conjugated protein of Shiga's bacillus (Morgan and Partridge 1942). The antigenic specificity of these endotoxins is in each case conferred by the polysaccharide component, which, as we saw in Chapter 7, may be regarded as a hapten. Toxic antigens of this type, characterized by different polysaccharide haptens, are widely distributed among the Gram-negative bacilli of the coli-typhoid group, and among other more distantly related bacteria. (For a discussion of mycobacterial and neisserial endotoxins, see Chapters 16 and 23.)

Mode of Action of the Toxins.

It has long been recognized that the healthy tissues of an animal can be poisoned by products of tissue breakdown in some other part of the body. One of the difficulties in determining the mode of action of bacterial toxins is the separation of the secondary effects due to tissue breakdown, from the primary effects of direct intoxication by some constituent of the bacterium. As an example of a secondary effect we may cite " leucotaxine " (Menkin 1938), a substance increasing the permeability of the walls of the blood capillaries, and " necrosin " (Menkin 1943, 1944), a necrosis-inducing substance associated with a protein. Both are products of inflamed tissue, irrespective of the primary inflammatory agent. The comparatively rapid action of some exotoxins, especially when administered intravenously, suggests that we are dealing with a primary effect. If, however, the effect is delayed for a few hours. it is impossible on *a priori* grounds to distinguish a latent period due to a slow penetration of toxin into, or a slow accumulation of toxin in, primarily susceptible tissue, from a latent period during which secondary toxins are being elaborated in primarily intoxicated tissues. The difficulty will probably be resolved by precise physiological and biochemical studies on the action of pure preparations of bacterial toxins. It must be realized, however, that the conspicuous effects that have been obtained in short-period observations of animals injected with relatively large doses of toxin may have little direct bearing on the relatively slow process of intoxication that occurs in natural bacterial infections (Wright 1942).

To postulate that toxins interfere with some essential metabolic processes in the animal tissues is merely another way of saying they are toxic. They may act by poisoning enzymes, rendering substrates insusceptible to enzymes, or altering the quantity or

quality of the products of certain enzyme processes. Both Wooldridge and Higginbottom (1938) and Peters and Cunningham (1941) have tested the effect of exotoxins on enzyme systems isolated from animal tissues. The former showed that the α-toxin of *Cl. welchii* depressed the aerobic oxidation of succinate by guinea-pig intestine, but only when present in very high concentration. Peters and Cunningham observed no change in a number of heart-muscle dehydrogenase systems to which diphtheria toxin had been added. Diphtheria induces in the carbohydrate metabolism of the rabbit changes attributable to abnormally large secretions of adrenaline (Corkill 1932, Corkill and Ochoa 1934, Yannet and Darrow 1933). Cross and Holmes (1937) demonstrated that isolated liver tissue from rabbits so intoxicated exhibited diminished respiration and diminished capacity to store glycogen and to synthesize carbohydrates from compounds like pyruvic and lactic acid. They were unable to decide whether the alterations were due to a direct damage of the liver cells, or to modification of the hormonal influences to which they are normally subjected.

Some of the specific physiological effects of the exotoxins of *Cl. welchii* in the whole animal have been studied by Kellaway and his colleagues (Kellaway, Trethewie and Turner 1940, Kellaway and Trethewie 1941). It is sufficient to note here that they range from direct action on the central nervous system, and the peripheral arterioles, to the liberation from tissues of histamine, adenyl compounds, and a substance causing slow contraction of the involuntary muscle. The α-toxin of *Cl. welchii* is of particular interest, being the first toxin whose action could be attributed directly to its enzymic nature. It is a thermostable lecithinase (Macfarlane, Oakley and Anderson 1941, Macfarlane and Knight 1941) to whose power of splitting lecithin and lecithoprotein complexes the α-toxin probably owes its hæmolytic, necrotizing and lethal properties.

The glycolipoid or, as they may be called, the lipo-polysaccharide endotoxins of the Gram-negative bacilli described above appear to act on the animal body in the same way, irrespective of the particular bacterium from which they are derived.

For example, injection of whole bacteria or of bacterial products is followed by changes in the concentration of blood sugar. The earlier findings in this respect (Menten and Manning 1925, Zeckwer and Goodell 1925, Menten 1926, Levine and Kolars 1926, Menten and King 1930) are difficult to correlate and interpret. Delafield (1931, 1932) found that intravenous injection of killed suspensions of various Gram-negative bacteria was followed by a marked hyperglycæmia, maximum in a few hours, then declining into a hypoglycæmic phase marked at 24 hours, after which, if the animal survived, the blood sugar returned to normal. The inorganic phosphorus levels fluctuated inversely as the blood sugar levels. Gram-positive bacteria do not appear to contain substances of this type (Delafield 1932, Olitzki, Avinery and Koch 1942). The endotoxins, as subsequent work has shown, are responsible for this effect (Delafield 1934, Boivin and Mesrobeanu 1934*b*, Morgan 1941, 1943, Favorite and Morgan 1942, Olitzki, Bendersky and Koch 1943, Leon and Morales 1943). The other non-specific effects of these endotoxins, depending on the dose and animal tested, include leucopenia, followed by a polymorphonuclear leucocytosis, and endothelial damage resulting in hæmorrhages, and sometimes focal necroses.

It is possible that adrenal stimulation and damage may play some part in the production of these effects (see Evans and Zeckwer 1927, Olitzki, Avinery and Koch 1942). In *Sh. shigæ* Olitzki and his colleagues (Olitzki, Leibowitz and Berman 1937, Olitzki and Avinery 1937) distinguish a toxic fraction and separate fractions producing leucopænia, glycæmia and hypothermia respectively. It is not certain how far their fractions were made up of complete endotoxin, and of breakdown products therefrom.

Other Active Constituents or Products of Bacteria.

We have already noted certain specific or non-specific biological characteristics of toxins; and many others, like the hæmolysins and leucocidins of *Staph. aureus*, could be instanced. In this section we are concerned with bacterial products

that are not markedly toxic in themselves, but act upon animal tissues and fluids in such a way as to suggest that they may influence the course of a bacterial infection. It is to be remarked, however, that the mere association of a biochemical property and pathogenicity either in a bacterial species or in the more virulent strains of a pathogenic species, is not by itself evidence that the property is concerned in infection by the species. As we have seen in the chapter on variation, latent activities of bacteria can be made manifest by the provision of suitable substrates, and though a virulent bacterium may exhibit an activity because a suitable substrate is present in the tissues of its host, it does not necessarily follow that the virulence depends on the capacity to attack the particular substrate; the capacity may in this respect be purely accidental.

Thus among the staphylococci, the more pathogenic *Staph. aureus* produces a coagulase that accelerates the clotting of human and rabbit plasma (Much 1908, Gross 1931*a*, *b*, Gengou 1933, Chapman *et al.* 1934). Since the formation of fibrin clots is a marked feature of *Staph. aureus* lesions in man and animals, it is natural to relate the two features. Nevertheless, Menkin and Walston (1935) could find no evidence that staphylocoagulase was concerned in the production of the staphylococcal lesions.

Tillett and Garner (1933) demonstrated an antigenic substance in hæmolytic streptococci that dissolves human fibrin (see also Tillett, Edwards and Garner 1934, Tillett 1935, 1938, Jablonowitz 1939). This fibrinolysin, though relatively heat-stable, behaves in many ways like an enzyme (see Mirsky 1944). It is produced by most Group A, C and G streptococci associated with suppurative and invasive types of human infection, while strains from feebler infections and throat-carriers are less actively fibrinolytic.

There is no doubt that active substances of the coagulase and fibrinolysin type are produced by a considerable variety of bacteria (see, for instance, Reimer 1936, Saski and Fejgin 1937, Christie and Wilson, 1941, Reed *et al.* 1943); and that a single bacterium can produce both types of substance. Again, each type of activity shows some degree of host specificity. Staphylocoagulase is inactive in guinea-pig plasma, and streptococcal fibrinolysins do not dissolve rabbit or fowl clots (see also Le Mar and Gunderson 1940). Milstone (1941) has shown one way in which this species-specificity may be determined. He found that human, but not rabbit, serum contains a heat-labile " lytic factor " associated with the euglobulin, in the absence of which streptococcal fibrinolysin failed to dissolve a pure fibrin clot. If the lytic factor were added to the rabbit fibrin, it became susceptible to the fibrinolysin. Smith and Hale (1944) found that susceptibility of sera to staphylocoagulase also depended on the presence in the serum of an activator. Human and rabbit sera contain the activator, which, when added to naturally insusceptible guinea-pig serum, renders it susceptible to coagulase. For the most part these activities are broadly associated with virulence, but highly virulent strains may not possess them, and vice versa; Sartorius (1936), for instance, could find no correlation between fibrinolytic activity and virulence in hæmolytic streptococci.

One of the most interesting classes of these relatively non-toxic bacterial products is that of the " spreading " or " diffusing " factors. Duran-Reynals (1928, 1929) described a substance in extracts of bull testicle that increased the area of the lesions following the injection of infective material into mammalian skin. As McClean (1930) and Hoffman and Duran-Reynals (1931) showed, the substance increased the permeability of the tissues, facilitating the spread of the fluids injected—whether solution of dye or toxins, a suspension of Indian ink, viruses or bacteria. Intradermal injection of fluid ordinarily raises a bleb that may take several hours to disappear. The presence of diffusion factor causes the bleb to disappear within a few minutes.

We can indicate only the broader relations of diffusing factors to infection. For detailed information the reader is referred to the review by Duran-Reynals (1942). The addition of diffusing factor to an inoculum of pathogenic bacteria or viruses enhances

the lesion only if the concentration of infectant is relatively great, or if its virulence is relatively high. If, for example, the bacteria are present in small numbers, or are only moderately virulent, the lesion may not develop at all, while injection without diffusing factor gives rise to a circumscribed lesion. Clearly the diffusing factor may inhibit the appearance of a lesion by spreading the pathogenic material in subinfective concentration throughout the tissues (see Thomas and Duran-Reynals 1935). On the other hand, if the bacterium is highly virulent, the lesion is not only larger than that produced in the absence of diffusing factor, but may have a more uniformly fatal outcome. Diffusing factors are elaborated by certain species of bacteria; *Staph. aureus* and *Str. pyogenes* (Duran-Reynals 1933); pneumococci (Goodner 1931, 1933); various clostridia and some strains of diphtheria bacilli (McClean 1936). Diffusing factor has not been found in members tested of the *Bacterium, Pasteurella, Rickettsia, Bacillus, Brucella, Vibrio, Hæmophilus* and *Neisseria* groups (see also Ungar and Bacharach 1942).

The identity of certain mammalian and bacterial diffusing factors with the enzyme hyaluronidase was first suggested by Chain and Duthie (1940), and although the parallelism is not complete (see Hobby *et al.* 1941, Meyer *et al.* 1941) the fact that many bacterial diffusing factors exhibit hyaluronidase activity and that growth of certain bacteria in media containing hyaluronic acid enhances the production of diffusing factor and hyaluronidase to the same degree (McClean 1941, McClean and Hale 1941) strongly suggests that the diffusion factors act by virtue of contained hyaluronidase. The intercellular ground substance of mesodermal tissue contains hyaluronic acid in a viscous polymerized form, and it appears that the enzyme hydrolyses the viscous polymer and thus permits the ready diffusion of fluid through the intercellular spaces.

It is evident that in certain experimental infections, the addition of hyaluronidase to the inoculum enhances the virulence of the contained organisms. The rôle of hyaluronidase in infections by organisms that produce it themselves is less clear. McClean and his colleagues (1943) detected large amounts of hyaluronidase in well-established local lesions by *Cl. welchii, Cl. septicum* and certain strains of *Cl. œdematiens*, and it is reasonable to postulate that in such circumstances the spread of the hyaluronidase-producing organisms would be facilitated by the enzyme. But it may be argued that, in the very early stages of a natural infection when the growing bacterium is present in small numbers, hyaluronidase, by promoting a rapid dispersal of the bacteria through healthy tissues, would expose invading organisms more thoroughly to the lethal action of the tissues.

The production of hyaluronidase, like that of coagulase and fibrinolysin, is associated with virulent species of bacteria, and to some extent with the virulent strains within a species. There is not, however, a complete correlation between invasiveness and hyaluronidase production. For example, some highly invasive strains of *Cl. welchii* produce none (Evans 1943); and the same is true of certain types of *Str. pyogenes* obtained from severe human infections (Crowley 1944). Moreover, bacteria like *Brucella melitensis* and *tularensis* and *Pasteurella pestis*, which are highly invasive in the accepted sense of the word, produce no hyaluronidase, while *Staph. aureus*, which is not markedly invasive, produces it in abundance. The rôle of hyaluronidase in infection cannot be settled until it is quite clearly shown that the virulence of a strain producing the enzyme is significantly altered by inhibition of its hyaluronidase-producing powers, or by neutralization of the hyaluronidase *in vivo*. Evans (1943) has made a start in this direction by showing that passive immunization of guinea-pigs with an anti-hyaluronidase serum does not materially alter the capacity of minimal infecting doses of *Cl. welchii* to engender gas gangrene, though his results are open to the criticism that the antiserum employed was too weak to exert a protective effect.

It is probable that pathogenic bacteria produce enzymic and other non-toxic substances which, by their action on the tissues influence the course of an infection (see, for example, Birch-Hirschfeld 1940). But in all cases we must guard against confusing an association with a causal linkage. As we have already emphasized,

a biochemical character may be genetically linked with characters that determine the virulence of an organism, and at the same time play no significant part in infection.

It seems quite possible that, wherever there is formed in the tissues a nidus of bacterial cells, alive or dead, there may result in the immediate neighbourhood a diversion of the normal metabolic processes sufficiently serious to derange the local cell activities. It is not impossible that the diffusion of bacterial enzymes might convert such a local effect into a more general one.

We should then regard the bacterial cell as endowed with an extensive armoury of chemical weapons of attack. These include (*a*) the filtrable toxins, diffusing freely from the site of infection and acting specifically on certain sensitive tissue cells. These are often lethal in extremely small doses; (*b*) the hæmolysins and leucocidins, acting directly on red cells and leucocytes, and hence influencing the course of an infection; (*c*) toxic substances contained in the bacterial cells, and not freely liberated into the surrounding fluid. Among these endotoxins are some, at least, of the somatic bacterial antigens, that are lethal in moderate doses and induce characteristic changes in the chemical constitution of the circulating blood; (*d*) various active substances which, though not directly toxic, may possibly influence the reactions of the tissues by inducing or inhibiting the clotting of plasma or lymph or by dissolving the fibrin of a clot already formed, or by increasing the permeability of the tissue spaces, or by any combination of these effects.

Hypersensitiveness and Allergy.

There are reasons, which will be discussed more fully elsewhere, for believing that the tissues may become sensitized during the course of a bacterial infection, so that a bacterial constituent which before called forth little or no response may act as a powerful stimulus. In some cases the vigorous response evoked is injurious to the host, so that a bacterial product which possesses little or no toxicity for a normal animal may be highly toxic for an animal which has become sensitized by infection. The well-known tuberculin reaction in the guinea-pig is a case in point.

Some Illustrative Examples.

We have described above the various bacterial factors which, so far as we know at the moment, are certainly, probably, or possibly concerned in the pathogenesis of infective diseases.

A few illustrative examples may serve to emphasize the more important points.

Botulism may be placed at one end of the scale, as an example of a pure toxæmia. It is not a true infection, but is closely analogous to the effects that may follow the consumption of such vegetable poisons as those produced by certain fungi or plants. There is no certain evidence that *Cl. botulinum* ever invades the tissues, or multiplies in them. Man is affected by eating food in which the organism has grown and produced its toxin.

Tetanus is one step removed, in that the bacillus must gain access to the tissues and multiply in them in order to produce its toxic effects; but its invasive powers are very slight. It usually gains access to the body as the result of some mechanical injury, and the local multiplication of the organism is in many cases assisted by gross injury to the tissues, by the injurious effects of some associated infection, or by the presence of some chemical agent, such as a calcium salt, which alters the local conditions to the advantage of the parasite.

Diphtheria takes us a little further along the scale. The bacillus is capable of implanting itself in the faucial region, and of spreading from host to host, by ordinary droplet infection or in similar ways. It has relatively slight but quite definite invasive powers. It causes a characteristic local lesion, and may occasionally invade other tissues and organs. Its lethal effect, however, depends almost entirely on its activity as a toxin-producer.

The hæmolytic streptococcus combines the activities of a typically toxigenic organism with those of the highly invasive group of bacteria. It produces a relatively heat-stable toxin, with a characteristic action on the skin, which is the cause of the typical toxic rash in scarlet fever; but it also invades the tissues freely. Indeed, highly virulent strains of the organism are among the most rapid and vigorous tissue-invaders with which we are acquainted in human pathology. In relation to this tissue invasion it is very probable that the hæmolysin, the leucocidin, and perhaps the fibrinolysin and the hyaluronidase produced by pathogenic streptococci play a significant part.

As we move along the scale we meet a variety of organisms whose pathogenicity seems to depend entirely on their power of spread and multiplication in the tissues, and whose more important effects seem to be localized to the areas in which such multiplication occurs. These differ among themselves in selective localization, and in the tissue reactions to which they give rise. Thus, staphylococci most commonly cause localized suppurative lesions, with a varying degree of lymphatic spread, which may sometimes be rapid and extensive. More rarely they give rise to a generalized infection of the pyæmic type, in which the cocci are carried from the original focus of infection in detached fragments of an infected thrombus. Here again, hæmolysin, leucocidin, and perhaps coagulase, fibrinolysin and hyaluronidase may play a part in determining the type of lesion in any particular case.

Finally, there are organisms, such as the tubercle bacillus, the leprosy bacillus and the *Tr. pallidum*, that tend to produce more chronic lesions of the granulomatous type. We know little as yet of the bacterial constituents that determine this particular type of tissue response, except in the case of the tubercle bacillus—see Chapter 59; and even there our knowledge is as yet very scanty. It seems probable that it is conditioned in large part by the absence of those bacterial constituents that determine the more rapid and vigorous response induced by organisms of the acutely toxic, pyogenic, or invasive type.

The defence mechanisms brought into play, and their relative importance, will clearly differ according to the type of infection. It is with these mechanisms that we shall be concerned in the following chapters.

SUMMARY

(1) An ability to gain access to the tissues, and to multiply in them to a lesser or greater degree is an essential attribute of a pathogenic organism. Some organisms produce their effects by the local production of a powerful toxin which passes into the tissues, and produces its toxic effects on cells remote from its site of origin. Others produce their main pathological effects at the site, or sites, in which they are multiplying. Of these latter, some give rise mainly to lesions limited to the near neighbourhood of their point of entry; others to lesions remote from this point, but characteristically localized in certain tissues or organs; others, again, to a

generalized bacteræmic infection. These different modes of attack are often combined in the case of a single infecting bacterium.

(2) The selective localization of bacteria in particular organs or tissues of the body is determined in part by characters inherent in the bacteria themselves. The anatomy of the infected host, the biochemical reactions of different tissues, and the defence mechanisms brought into play, combine with these inherent bacterial characters in determining the exact distribution of lesions encountered in each particular case.

(3) Pathogenic bacteria differ in the cellular reactions to which they give rise. These differences may be highly characteristic.

(4) Among the bacterial toxins are some which are characterized by the ease with which they may be separated from the bacterial cells which produce them. Under suitable conditions they diffuse into a fluid medium and may be obtained from the cells by simple filtration. Toxins of this class are commonly referred to as *exotoxins*. They are usually characterized by possessing a specific pharmacological action, and by being actively antitoxinogenic. Their Minimal Lethal Dose is generally small, sometimes very small. They are in many cases thermolabile, being inactivated by temperatures in the neighbourhood of 55° C. The more fully investigated exotoxins are predominantly protein in nature.

(5) Apart from these toxins there is another class of toxic bacterial products which are characterized by remaining incorporated in the substance of the bacterial cells. They can be obtained in a state of solution, or perhaps suspension, only by extraction or manipulations that result in the disintegration of the cells. They do not, in general, exert any characteristic pharmacological action by which they can be differentiated from one another. They are feebly antitoxinogenic. Their Minimal Lethal Dose is usually large. They are relatively heat-stable, withstanding temperatures of 80°–120° C. for an hour or more. They are often referred to as *endotoxins*. The more fully investigated endotoxins have proved to be predominantly lipo-polysaccharide in nature; some of them contain protein-like substances that are essential to the constitution of the toxic complex.

(6) Although it is often an easy matter to assign a toxic bacterial product to one of these categories, this is not always the case, since the criteria referred to above are by no means constant. It would, indeed, be very difficult to give any satisfactory definition of an endotoxin. Within this category we may include certain of the somatic antigens of bacteria that have been found to be highly toxic in the form in which they occur in the bacterial cell.

(7) There are other substances in bacterial cells which are not in themselves toxic, but whose nature—the capacity to induce or inhibit the coagulation of plasma or lymph, to dissolve a fibrin clot, or to increase the local intercellular permeability of tissues—suggests that they may influence the course of the infective process; and it is possible that other enzymes concerned in bacterial metabolism may have a like influence in infection by alteration of the metabolism of the tissues.

(8) As the result of infection the tissues of the host may become hypersensitive to the infecting bacteria or to their products. Such sensitization may play an essential part in some of the phenomena of infective disease.

CHAPTER 45

THE MECHANISMS THAT HINDER OR PREVENT THE ACCESS OF BACTERIA TO THE TISSUES

As noted in the previous chapter, an ability to gain access to the tissues and to multiply in them to a lesser or greater degree is an essential attribute of a pathogenic organism. It is logical to commence our study of the defence mechanisms of the host by considering the barriers that are opposed to the ingress of bacterial parasites from the outside world. Unfortunately our knowledge is here at its sketchiest. Most studies of experimental infections in animals have been concerned with reactions that take place within the tissues. It is only within recent years, and in the hands as yet of relatively few workers, that any serious attempt has been made to study systematically the mechanisms concerned in the first line of defence.

It will be convenient to take in turn the various body surfaces and portals of entry, and to summarize very briefly our scanty knowledge of their behaviour towards bacteria that establish contact with them.

The Skin.—It needs only the most casual acquaintance with the ordinary accidents of life to establish the value of an intact skin as a barrier against bacterial infection. The inability of the deeper tissues to protect themselves against the free access of bacteria from the outside world set a sharp limit to major surgical interference in pre-Listerian days. There can be little doubt that the skin functions in the main as a simple mechanical barrier, but it has recently become clear that the efficacy of this barrier is enhanced by a complex biological mechanism which enables the skin surface to free itself rapidly from the majority of those bacteria that are continually impinging upon it.

The skin has certain self-sterilizing powers. Colebrook (1930) found that hæmolytic streptococci were rapidly killed on the skin of the normal hand. Three minutes after swabbing the finger lightly with a broth culture, 30 million cocci could be recovered by swabbing with sterile broth. One hour later 1·7 million cocci were recoverable; two hours later, 7,000 cocci. Similar results were obtained with *Proteus vulgaris*, *Bact. friedlanderi* and *Bact. coli.*, and control experiments on other surfaces showed that the bacteria had not died by desiccation. Though the skin will free itself to a considerable extent from bacteria that form no part of its normal flora, its reactions are entirely different towards those species that habitually live on it. No amount of washing, nor any of the chemical disinfectants commonly used for sterilizing the hands in obstetrical practice, will remove from the skin the numerous staphylococci and bacilli that normally vegetate thereon. These organisms, which were named by Price (1938) the "residents," as opposed to the "transients" like *Str. pyogenes*, probably lie in the ducts of the sweat and sebaceous glands, in hair follicles, or among the cells of the stratum corneum, though Price himself suggests that they are in some intimate manner adherent to the skin surface.

Arnold, Gustafson and others, 1930 (see also Karns and Arnold 1931), record a more detailed series of observations along similar lines. About 99 per cent. of *Chromobacterium prodigiosum* could not be recovered in 20 minutes, and all were dead within 30 minutes. On the palmar surface of the clean hand *Bact. coli*, *Salm. typhi* and *Salm. enteritidis* could not be detected after 10 minutes, though in certain regions, under the nail-tip and along the lateral margins of the finger nails, the bacteria persisted longer. There was a rapid initial reduction of *Staph. aureus* on the palmar surface of the hand, but small numbers persisted for long periods. The skin of dirty hands had less self-sterilizing power, the reduction of *Salm. enteritidis* being 5 per cent. in 20 minutes; after washing the reduction was 100 per cent. in 20 minutes. Fifteen minutes after the death of the skin, most of the bactericidal action for *Bact. coli* had disappeared

The readiness with which *Str. pyogenes* is killed on the skin has been partly elucidated by Burtenshaw (1938, 1942) (see also Williams *et al.* 1943) who extracted, from normal living or dead skin, substances resembling long-chain fatty acids and soaps that were markedly bactericidal for *Str. pyogenes*, but not for *Staph. aureus*.

Arnold and his colleagues attach considerable importance to the effect on bacteria of the pH of the skin, which is usually acid (5·8–5·2, see Schade and Marchionini 1928). Marchionini and others (1938), using a skin electrode, found the greater part of the skin surface was acid, the pH in some spots being as low as 5 or even 3. There were alkaline areas in the axillæ and groins, between the toes and on parts of the foot, which they regarded as gaps in the "acid coat" that constitutes a defence against infection of the skin. The flora of skin was scantier in the acid areas and, in these, applied *Chromobacterium prodigiosum* disappeared more rapidly than in the alkaline areas. After induced sweating the skin increased in acidity, and was more bactericidal. Bergeim and Cornbleet (1943) attribute the acidity to the lactic acid excreted in sweat, and to the volatile acids formed from it by bacterial action. The former is active in regions where the pH of the skin is 5 3 or less; at a higher pH, it dissociates and loses much of its bactericidal power. The latter are active at a pH of 5·3 to 6·2, and will consequently be effective in the more alkaline areas of the skin.

(For general discussion of the protective powers of the skin see also Vierthaler 1940, Neufeld 1942).

It should be noted that not only may bacteria be killed, but viruses may be inactivated on skin. Influenza virus, for example, in one series of experiments, could not be detected 10 minutes after application to the human skin (U.S. Navy Medical Bulletin 1943); though in another series (Parker and MacNeal 1944) suspensions of virus in the allantoic fluid of the chick survived 45 to 50 minutes on the skin of the hand.

Fleming (1922, 1929, 1932) has recorded the presence in tears, in nasal secretion, and in many tissues including the skin, of a relatively thermolabile substance which, in high dilution, causes the lysis of certain non-pathogenic bacteria, and in particular of an organism to which he gave the name of *Micrococcus lysodeikticus*. This substance, *lysozyme*, is an enzyme (Meyer *et al.* 1936, Abraham 1939) which appears to initiate lysis by splitting certain polysaccharide components of susceptible bacteria (Epstein and Chain 1940). It is active against some strains of staphylococci, and of intestinal streptococci of human origin. In high concentration it acts, though less energetically, on other pathogenic bacteria. It is natural to inquire whether it plays any part in the self-disinfecting action of the human skin. If so, it would seem that its rôle is relatively unimportant; since Colebrook (1930) records that many of the bacteria that are rapidly removed are not susceptible to its action, while *Micrococcus lysodeikticus* itself disappears less rapidly from the skin than such species as *Str. hæmolyticus*, *Bact. coli* or *Proteus vulgaris*.

The Mouth, Stomach and Intestinal Tract.—When bacteria gain access to the mouth, provided that they are not introduced as constituents of some food or drink that is immediately swallowed, they adhere to the mucus with which the lining epithelium is plentifully covered.

A series of careful studies by Bloomfield (1922*a*, *b*, *c*) have enabled him to trace in some detail their subsequent fate. In an initial series of experiments carbon particles were placed on the tongue, on the palate, in the sublingual space, on the mucosa of the cheek, on the posterior pharyngeal wall, or on the tonsil, and their subsequent movement was carefully observed. It was found that there was little or no tendency for the particles to spread at random over the surface of the mouth, but that they were removed from the various sites of implantation in an orderly manner. The general path of removal was directly backwards. There was no forward dissemination nor was there any tendency to wide lateral spread—carbon placed well to one side of the tongue near its tip did not, for instance, cross the mid-line. The paths of transit from the tongue, sublingual space and palate all converge at the base of the tongue. The tonsils, protected by the faucial pillars, occupy a position that is out of the way of these lines of passage so that under normal conditions particles that are deposited on the tongue are swept past them. The currents that bear the particles backwards are almost certainly the result of suction, set up by the lips, cheek, tongue and palate ; and particles are removed with particular rapidity from the sublingual space and from the lateral buccal mucosa, where the flow of saliva is maximal and the local formation of the mucosa is least favourable to retention. Particles placed directly on the tonsils are in part removed rapidly by the general flushing action of the saliva ; but those that once gain lodgment remain relatively stagnant for a considerable period of time. Having reached the base of the tongue the particles are periodically swallowed. In general, carbon particles are almost completely removed from the mouth within 15 to 30 minutes. Subsequent experiments with *Sarcina lutea* showed that bacteria introduced into the mouth were removed in the same fashion as carbon particles. Attempts were made to alter the flora of the tongue by thorough and repeated washing. It was found that the greater part of any bacteria artificially implanted could be rapidly removed in this way, but no amount of washing would produce any significant change in the character or number of the normal lingual flora. It would appear that bacteria entering the mouth are unable to persist on any of the mucous surfaces for more than a few hours unless their biological characters are such as to allow of successful colonization. Once colonized they become part of the local flora, and can no longer be dislodged by any simple mechanical means, nor probably by any ordinary disinfectant.

Human saliva is to some extent bactericidal. It is said to moderate the virulence of diphtheria bacilli given intradermally in guinea-pigs (Bézi 1932), and to be bactericidal for *C. diphtheriæ* (Dold and Weigmann 1934, Weigmann and Koehn 1936, Weigmann and Noeske 1937), and for a wide variety of cocci and intestinal pathogens (Dold *et al.* 1936). Dold and his colleagues gave the name " Inhibine " to the bactericidal principle of saliva, which they found to be thermolabile, and protein in nature. Casassa (1937) found the salivary principle to be heat-stable ; while Schäfer (1936) failed to confirm Dold's findings. (See also Auerswald 1938.)

Once bacteria have been swallowed they are subjected in the stomach and upper part of the duodenum to the action of the gastric juice, with its high hydrogen-ion concentration. It has long been recognized that the gastric secretion imposes a barrier to the passage of bacteria from the mouth to the intestine, but the careful studies of Arnold and his colleagues (Arnold 1926, 1927, 1928, 1929, Arnold and Brody 1926*a*, *b*) have placed our knowledge on a more detailed basis. By fixing various segments of the gastro-intestinal tract of the dog to the skin of the abdomen they were able to withdraw samples of the contents by sterile puncture as desired, and thus to determine the nature of the normal flora in relation to the acidity or alkalinity of the intestinal contents, and also the fate of other bacteria when administered by the mouth.

Table 66 shows the relation between the hydrogen-ion concentration of the intestinal contents and the prevailing bacterial flora at different levels.

TABLE 66

Portion of Small Intestine.	pH of Contents.	Bacterial Flora
Duodenum	5·2–6 0	Few Gram-positive cocci.
Jejunum, upper half . .	5·5–6·5	,, ,, ,, ,,
Jejunum, lower half . . .	6 0–7·0	Gram-positive cocci, few Gram-positive and Gram-negative bacilli.
Ileum	6 8–8·0	Rich and varied bacterial flora.

Using as test organisms *Chromobacterium prodigiosum* and *Ps. pyocyanea*, it was found that these bacteria, when introduced in watery suspensions into the empty stomach of a dog 12 to 18 hours after a meal, failed to reach the cæcum. Introduced in an alkaline buffered watery suspension or in alkaline buffered milk they reached the cæcum in large numbers. (See also Teale 1934 and Chapter 90).

Whether the bactericidal action of the duodenal contents is entirely determined by its hydrogen-ion concentration, is, perhaps, open to question (see Meyer and Löwenberg 1928).

Garrod (1937) found that gastric juice was markedly bactericidal for a number of organisms that infect by the mouth. *Br. abortus* was most susceptible; and after it, in diminishing order of susceptibility, *Br. melitensis*, *Salm. typhi*, *Salm. typhi-murium* and *Sh. flexneri*.

With regard to the possible effect of Fleming's lysozyme in the stomach and intestine, Goldsworthy and Florey (1930) have studied the distribution of this substance in mucus and mucosal extracts from several animal species, using as test organisms *Micrococcus lysodeikticus* and a series of unidentified susceptible bacteria isolated from the air of the laboratory. In the cat, no lysozyme could be detected in mucus from the stomach or colon, though small amounts could be demonstrated in saline extracts of the dried mucosæ. In the dog, detectable amounts were present in the mucosa of the intestinal tract, more in the colon than in the stomach. In the rabbit, the mucosal extracts were actively lytic. The colon was more active than the stomach, the small intestine falling between the two. In the guinea-pig, on the other hand, the mucosa from the stomach was more active than that from the intestine. What part this substance plays in eliminating susceptible species from the intestinal flora it is, however, impossible to say.

Quite apart, however, from the action of the contained lysozyme, there can be no doubt that the mucus itself provides a very efficient and important cleansing and protective mechanism. Florey (1933) has studied this mechanism in some detail. He finds that the mucus does not form a uniform coating over the epithelial cells of the mucosa, but is present in the form of a lace-like mesh-work spread over the mucosal surface. The villi free themselves from any small adherent particles by movements that bring the particles into contact with the mucus, to which they adhere. The mucus, with the adherent particles, is then rolled up into small masses by the intestinal movements, and is propelled onwards by the peristaltic movements of the bowel. Non-pathogenic bacteria, when introduced into the intestinal lumen, appear to behave very much as inert particles, except that those sensitive to lysozyme are dissolved when lysozyme is present. When a thick suspension of a pathogenic organism, such as *Salm. typhi-murium*, is introduced into an intestinal loop the resulting changes are very different. There is a considerable exudation of phagocytic cells into the gut lumen, and in places the epithelial cells desquamate, leaving bare the underlying stroma. Most of the mucosa, however, preserves its epithelial covering completely; and it would appear that the bacteria not infrequently enter, and pass through, the epithelial cells themselves.

It is of obvious interest to inquire whether those procedures that alter the normal conditions in such a way as to allow bacteria to pass alive through the

stomach and duodenum to the lower segments of the intestine have any effect in promoting their passage through the intestinal mucosa to the lymphatics and blood stream.

Arnold (1928) has studied this problem experimentally. *Bact. coli* and *Chromobacterium prodigiosum* were injected with minimal injury into a dog's duodenum, and counts were made of the bacteria in the lymph collected from a canula inserted into the thoracic duct. The results are summarized in Table 67. It will be noted that alkalinization alone does not suffice to induce the transit of bacteria from the intestinal lumen to the lymphatics, but that addition of bile, or still better of egg white, so alters the conditions at the mucosal surface that such passage occurs. The negative findings with the other suspending fluids employed are in accord with those of Neisser (1896) and of Teale and Embleton (1914). It would appear that only under quite exceptional conditions is the intestinal mucosa permeable to living bacteria; and it would seem (Nedzel and Arnold 1931) that raw egg albumin is peculiarly potent in inducing the passage of bacteria not only from the intestinal lumen to the lymphatics and the blood, but in the reverse direction from the blood stream to the intestinal lumen.

TABLE 67

Solution injected with Bacteria.	Average No. of Bacteria in Lymph per ml.	Time of Appearance after Injections
Alkaline solution and egg white. .	500 to 1,000	First 5 mins. and lasting for 30 mins.
Neutral solution and egg white . .	None	—

Neutral solution	None	—
Alkaline solution and bile . . .	50 to 100	First 5 mins. and lasting for 20 mins.
Neutral solution and bile. . . .	3 to 5	During first 30 mins.
Alkaline solution and dog's serum .	None	—
Neutral solution and dog's serum .	None	—

The Nose, Nasopharynx and Respiratory Tract.—The nasal cavities are in part protected from air-borne bacteria by the anatomy of the anterior nares. The greater part of the inhaled bacteria appear to be arrested at or near the nasal orifices (see Thomson and Hewlett 1896). Those that pass beyond this point adhere to the film of mucus that covers the nasal mucosa, and are then swept back—in this case by the current set up by the ciliated epithelium—towards the naso- and oro-pharnyx, where they join the bacteria being swept back by suction currents from the mouth (see Bloomfield 1919, 1922*d*). Droplets and droplet nuclei produced by spraying a culture of *Chr. prodigiosum* into air, in numbers up to 700 per litre, were found by Rooks (1939) to be filtered out in the nasal passages with an efficiency of 87·5 per cent. The efficiency was less—62·0 per cent. —when air containing only droplet nuclei was tested.

Whether mechanical clearance is the only factor concerned is again uncertain. Arnold, Ostrom and Singer (1928) introduced *Chromobacterium prodigiosum* and *Bact. coli.* by spraying, into the nose of men, rabbits, dogs and guinea-pigs, and noted their rapid disappearance. They state that swabs taken from the posterior pharyngeal wall gave no indication that there was any extensive passage of the bacteria to the throat; but they were unable to detect in nasal washings or secretions any substance that was bactericidal to the test organisms employed. It may be noted that the rate of disappearance recorded by Arnold and his colleagues—a diminution in numbers during the first 5 minutes, and total disappearance within half an hour—was more rapid than that recorded by Bloomfield—

little change in 2 hours but almost complete disappearance in 24. This slower rate of elimination was also noted by Bloomfield in the case of particles of kieselguhr placed on the nasal septum. The route followed by substances introduced into the nose to some extent depends on the animal tested, the nature of the substance and the method of its administration. Rake (1937), for example, records a ready intercellular penetration of the olfactory mucosa of mice by pneumococci, *Salm. enteritidis*, particles of Prussian blue and the virus of equine encephalomyelitis, but only slow penetration by rabies and certain other viruses; while in rabbits, virulent pneumococci penetrate the nasal mucosa only if the containing fluids are kept in prolonged contact with it (Cannon and Walsh 1937).

Lysozyme is known to be present in high concentration in the nasal secretions, and it is probable that it plays a part in freeing the nasal cavities from those species of bacteria against which it is active. A substance resembling Dold's Inhibine in bactericidal power has been described in the nasal secretion of normal persons (Ignatius 1936). Burnet, Lush and Jackson (1939) found a heat-labile, possibly enzymic, substance in nasal secretion that inactivated certain viruses, notably those of influenza, herpes and poliomyelitis. Vaccinia virus was insusceptible to its action.

Whatever may be the nature of the complex of mechanisms involved there is every reason to suppose that the same result is attained in the nose as in the mouth. The majority of bacteria that enter at the external nares are removed or destroyed, and fail to obtain any but the most transient footing among the normal nasal flora; those that survive and multiply do so because they are in some way adapted for successful colonization, and once such colonization has occurred they may persist for an indefinite period of time.

The conditions in the nasopharynx have been sufficiently dealt with in considering the elimination of bacteria from the mouth.

It would appear (Calamida and Bartarelli 1902) that the accessory nasal sinuses are normally sterile.

There is little doubt that in health the trachea and bronchi contain few if any living bacteria (see Thomson and Hewlett 1896, Bloomfield 1922*d*); and it is probable that the main protective mechanism consists in the filtering action of the nasal passages combined with the adherence of bacteria which pass the posterior nares, or are drawn in *via* the mouth, to the pharyngeal or upper laryngeal mucosa. It is, however, quite certain, from the ordinary experience of the *post-mortem* room, that dust particles, and hence presumably bacteria, reach the lungs in numbers that, if minimal in any short period of time, attain a considerable total in the course of months or years.

Under certain conditions, mainly experimental (see Nenninger 1901, Paul 1902, Quesnil 1902, Wherry and Butterfield 1920, Bloomfield 1922*d*, Trillat 1923, Stillman and Branch 1926), bacteria inspired as dust or droplet nuclei may reach the peripheral alveoli of the lung in relatively large numbers. Jones (1922) records that the lungs of normal herbivorous laboratory animals contain bacilli derived from the dust present in their dry food-stuffs. It appears, however, that those which penetrate so deeply never form more than a small fraction of the total number inspired. Cralley (1942) has shown that when droplet nuclei made from cultures of *Chromobacterium prodigiosum* are inhaled by the rabbit more than 96 per cent. are retained in the upper respiratory tract. Of the bacteria contained in those nuclei that reach the lung alveoli, 90 per cent. disappear in 3 hours, and none can be found after 12 hours. Once past the vocal cords, the inspired organisms are probably dealt with in three ways. They may adhere to mucus and be expec-

torated; they may be driven upwards by the ciliated epithelium (Florey, Carleton and Wells 1932, Barclay and Franklin 1937) which extends as far down as the smaller bronchioles; or they may reach the alveoli, and be ingested by phagocytic cells, and removed *via* the lymphatic plexus to the regional lymph nodes. It is probable that ingestion by the alveolar macrophages is in some cases followed by intracellular digestion of the bacteria *in situ*. There is little evidence of an immediate bactericidal mechanism in the lungs, though Dold (1943) found that cultures of *B. anthracis* and *Chr. prodigiosum* were rapidly killed when applied to the inner surface of the partly excised trachea of the guinea-pig. From the fact that autoclaving of the tissue destroyed its bactericidal power, he inferred the presence of an "inhibine" similar to that reported in saliva.

Fluid that contains bacteria, once it is past the epiglottis, flows readily to the terminal parts of the lung, the distribution depending to some extent upon the posture of the animal. Infection of the lung is more easily achieved by instillation of fluid than by inspiration of bacterial dusts or mists (see Webster and Clow 1933, Cannon and Walsh 1937).

The Conjunctivæ.—It is convenient to consider the conjunctivæ in connection with the upper respiratory tract. The mechanical flushing action of the tears is an obvious phenomenon, and there is little doubt that the main route of removal is *via* the lachrymal duct.

Maxcy (1919) was able to recover *Chromobacterium prodigiosum* from the nose within 5 minutes after its introduction into the conjunctival sac. Stort (1891) failed to recover *Bact. coli* from the rabbit's conjunctiva 1 hour after its implantation; but found that it persisted for a much longer time if the lachrymal duct were previously tied.

Tears have the highest lysozyme content of any secretion yet examined. At a dilution of 1 : 40,000 they may cause complete lysis of a suspension of *Micrococcus lysodeikticus*. There can be little doubt that this agent suffices to rid the conjunctiva of many of the organisms that come in contact with it, and that it plays a part in the local defence of this region against certain pathogenic bacteria (see Ridley 1928).

The Genital Tract.—It is probable, though there is no definite evidence on the point, that the external genitals, so far as they are covered with a complete dermal layer, share the bactericidal action of the skin elsewhere. There are probably additional selective factors—favourable or inhibitory for particular bacterial species—resulting from localized glandular secretions, or from differences in the amount of moisture in the skin.

The urethra in the male and female is normally sterile, or contains in the neighbourhood of the meatus a few staphylococci and diphtheroid bacilli. The mechanical flushing action of the urine, combined perhaps with its slightly acid reaction (pH 6·0), is probably an important factor. Dold and Deck (1941) have described a heat-stable type of inhibine in fresh urine, active against a wide variety of pathogenic species.

The vagina has a highly characteristic flora, consisting largely of aciduric bacilli of the Döderlein type (see Küster 1929, Schultheiss 1929). The normal vaginal secretion has a marked bactericidal action on many species of bacteria. Thus Menge (1894) found that *Ps. pyocyanea*, staphylococci and streptococci introduced experimentally into the vagina could not be recovered after 21 to 26 hours (see also p. 1210).

Bacterial substances have been described in cow's milk, active against cocci and coliform bacilli (see Hobbs 1939, Morris 1943, 1945, Green and Pauli 1943). It is possible that in man such substances may contribute to the defence of the lactating mammary gland against certain infections.

The Efficiency of the Bactericidal or Inhibitory Mechanisms Operating on Body Surfaces.

It is extremely difficult to assess the relative protective value of the factors that we have described above, as compared with the mechanisms that we shall discuss in subsequent chapters. It is obvious that they often fail; but how frequently they succeed we cannot tell.

That they are of real importance can easily be shown experimentally by noting the different doses of bacteria that are required to induce experimental infection by different routes.

To take a single example from many available, the dose of *Salm. typhi-murium* that will, on the average, lead to a fatal infection when injected intraperitoneally into a mouse of 18–22 gm. is somewhere between 1,000 and 1,000,000 times smaller than the dose that will lead to the same result when administered by the mouth. A series of observed figures for groups of 85 mice per dose (intraperitoneal injection) and of 75 mice per dose (*per os* infection) are given in Table 68.

TABLE 68

SHOWING THE PERCENTAGE MORTALITIES OBSERVED IN GROUPS OF MICE AFTER THE ADMINISTRATION OF VARIOUS DOSES OF A VIRULENT STRAIN OF *Salm. typhi-murium* INTRAPERITONEALLY OR *per os*.

Number of Bacilli administered.	Mortality per cent.	
	Intraperitoneal.	*Per os.*
1,000,000,000	Not tested	48·75
10,000,000	98·8	28·25
100,000	84·7	22·50
1,000	65·9	15·00
10	28·2	Not tested

SUMMARY

There are a series of mechanisms, concerning the exact nature of which we as yet know relatively little, that tend toward the mechanical removal or local destruction of most of those bacteria that reach the various body surfaces from the outside world. These mechanisms vary in nature from one locality to another; each body surface—the skin, the conjunctivæ, the mucous membranes of the nose, mouth, pharynx, intestinal tract, genital tract and so on—tends to develop and maintain its own characteristic bacterial flora, the flora of any one locality differing both qualitatively and quantitatively from that of another, and the flora of a particular locality (say the nasopharynx) showing minor but significant differences as we pass from one person to another, or study a single person over a prolonged period of time.

The resistance thus afforded to colonization of bacterial immigrants is certainly an important factor in the body's first line of defence, but its effectiveness in relation to any particular natural infection, or under any specified set of conditions, cannot at present be estimated with any accuracy. We know only that this barrier is, in fact, often penetrated, and that the fate of the host then depends on the mechanisms of antibacterial or antitoxic immunity that we shall consider in subsequent chapters.

CHAPTER 46

THE MECHANISMS OF ANTITOXIC IMMUNITY

For our immediate purpose this type of immunity may be dealt with very briefly.

Apart from certain cases of natural insusceptibility, such as the insusceptibility of birds and of cold-blooded animals to tetanus toxin (Vaillard 1892), immunity to bacterial exotoxins depends on the presence in the circulating blood of antitoxins which exert a specific neutralizing action. These antitoxins may have been naturally acquired, as the result of past infections, overt or latent ; or they may have been produced in response to purposeful immunization with modified or unmodified toxin. They can be passively transferred from one animal to another—naturally from mother to offspring *via* the placental vessels or in the colostrum, artificially by injecting an antitoxic serum into a susceptible host.

The original observations on this type of immunity were made by von Behring and Kitasato (1890), who showed that the sera of animals that had received repeated injections of non-lethal doses of tetanus toxin or of diphtheria toxin had acquired the property of specifically neutralizing these toxins and thus preventing their poisonous effects.

Since that time a number of antitoxic sera have been prepared, and applied in prophylaxis or treatment. We are here concerned only with anti-exotoxins—in the sense in which these were defined in Chapter 44. Among these we should include —in addition to diphtheria and tetanus antitoxins—the antitoxins that neutralize the erythrogenic toxin produced by the hæmolytic streptococcus and the toxins of the *Staphylococcus aureus*, of Shiga's dysentery bacillus, and of a variety of pathogenic anaerobes, such as *Cl. welchii*, *Cl. septicum*, *Cl. œdematiens* and the lamb-dysentery bacillus. The antitoxin which neutralizes the toxin of *Cl. botulinum* is, of course, a typical anti-exotoxin ; but, as we have explained above, it is doubtful whether *Cl. botulinum* should be included among the pathogenic bacteria in the ordinary sense, since there is little evidence that it is capable of giving rise to infection *in vivo*.

A characteristic of antitoxic immunity is the relatively low concentration of antitoxin in the circulating blood which suffices to afford protection against natural infection, provided that it has been produced as the result of active immunization. In the particular case of diphtheria in man, we have good reasons for believing that less than 0·01 unit of antitoxin per ml. of blood serum will render a person immune to the natural disease (see Glenny 1925). Under such conditions the initial toxin produced is neutralized as it passes from the site of infection before it reaches the susceptible cells. But it is clear that this small amount of circulating antitoxin will not suffice for long, and that more will be needed to neutralize additional toxin as and when it is produced. An actively immune person or animal

differs from a non-immune not only in possessing circulating antitoxin but in the readiness and rapidity with which more antitoxin is produced in response to the stimulus provided by the access of toxin to the tissues (see Chapter 50). The equilibrium between the rate of toxin-production by the bacterium and the rate of antitoxin-production by the host is, in the immune animal, readjusted to the host's advantage. A degree of antitoxic immunity that afforded ample protection against infection with a toxigenic organism could of course be broken down by the inoculation, in a single dose, of an overwhelming amount of toxin.

Although the efficacy of antitoxic immunity is, in the main, determined by quantitative relationships of this kind, there can be little doubt that qualitative differences between one antitoxin and another affect the firmness of toxin-antitoxin union, and so the degree of protection afforded.

It was pointed out many years ago that the curative effect of antidiphtheria sera, as judged by experiments on laboratory animals, did not always run parallel to the antitoxin content as assessed by the ordinary technique (see, for instance, Kraus and Schwoner 1908, Kraus and Baecher 1913). Kraus and his colleagues suggested that one important quality of an antitoxic serum, not measured or expressed in the official standardization in terms of Antitoxin Units, was the character that determined the *rate* of neutralization, and for this character they proposed the name *avidity*. The conception of avidity has been considerably modified, and rendered far more precise, by later observations recorded by Madsen and Schmidt and by Glenny and his colleagues.

Madsen and Schmidt (1929) found that, with some antitoxic sera, toxin-antitoxin mixtures that were neutral as judged by subcutaneous injection in the guinea-pig might produce a fatal toxæmia when injected intravenously into rabbits. Glenny and his colleagues (see Glenny and Barr 1932*a*, *b*, Glenny *et al.* 1932) note that, with sera of this kind, it is possible to prepare mixtures such that rabbits will survive the intravenous injection of 10 ml. but not of amounts varying from 0·001 ml. to 0·5 ml. The greater dilution of the small inocula in the rabbit's circulating blood apparently results in the dissociation of a lethal dose of toxin. Glenny and his colleagues have devised a method for estimating the avidity of antitoxic serum in terms of a *dilution-ratio*, which they define as the ratio of the amount of antitoxin necessary to form a neutral mixture with one L_r dose of toxin in a total volume of 2 ml., to the amount necessary to form a neutral mixture with the same amount of toxin in a total volume of 200 ml., neutrality being determined in each case by the injection of 0·2 ml. of the mixture into the skin of a guinea-pig. Although Glenny and Barr, in agreement with Madsen and Schmidt, note that avid sera commonly give rapid flocculation when examined by Ramon's method, they regard firmness of union, rather than rapidity of reaction, as the essential character in avidity. They note that the avidity of antitoxic sera appears to be determined, at least in part, by the type of serum protein with which the antitoxin is associated. Thus (Barr and Glenny 1931*a*, *b*, Glenny and Barr 1932*a*, Glenny *et al.* 1932), if successive globulin fractions are precipitated with increasing amounts of ammonium sulphate, the earlier fractions are more avid than the later. Avidity is sometimes a property of a particular electrophoretic fraction of an antiserum (see Chapter 7). According to Kekwick and his colleagues (1941) the γ-globulin of diphtheria antitoxic serum is more avid, flocculates more rapidly *in vitro*, and has a greater combining power than the α-globulin (see also McSweeney 1941). These phenomena are by no means confined to the particular case of diphtheria toxin and antitoxin. It would seem indeed that non-avid sera are more frequently met with among antitoxic sera of other types (Glenny *et al.* 1932). (See also Chapters 47 and 55 for analogous observations in the case of antibacterial and antiviral sera.)

The increased resistance afforded by specific antitoxic immunity is determined almost entirely by the interception and neutralization of the toxin before it reaches

the susceptible cells. Once these have been attacked, the antitoxin is relatively ineffective.

Glenny and Hopkins (1925) have studied the effect of the administration of various doses of antitoxin at different times after the intradermal injection of a Schick dose of diphtheria toxin into a guinea-pig. This amount of toxin produces a characteristic local reaction at the site of inoculation; 0·001 unit of antitoxin is sufficient to prevent this reaction if the toxin and antitoxin are mixed together before inoculation. If, however, the toxin is injected before the antitoxin, neither 10 units of antitoxin injected intravenously 15 minutes later, nor 1,000 units injected intravenously 30 minutes later, are sufficient to prevent the appearance of a small reaction at the site of the injection of the toxin. The size of the reaction is, however, very greatly reduced as compared with that which occurs when no antitoxin is given. If 10 units of antitoxin are administered intravenously 30 minutes after the intradermal injection of the toxin, or 1,000 units intravenously after 1½ hours, or intramuscularly after 45 minutes, the size of the lesion is reduced to about half its usual diameter. A slight reduction in the size of the reaction is obtained if 1,000 units are injected intravenously after 2½ hours, or intramuscularly after 1¾ hours; but the subcutaneous injection of this amount of antitoxin 15 minutes after the intradermal inoculation of toxin leads to no reduction in the size of the reaction. We may note the relatively enormous dose of antitoxin that is required to neutralize the effect of the toxin under the conditions of this experiment; 1,000 units of antitoxin are equivalent to 1,000,000 times the dose of toxin injected into the skin, yet this amount administered intravenously 30 minutes after the intradermal injection fails to suppress completely the local toxic effect. Friedemann and Zuger (1939) record analogous results in rabbits (see p. 1060).

From a consideration of the amounts of intravenous antitoxin required to protect dogs from locally injected tetanus toxin, Abel and Chalian (1938) concluded that the protective dose increased exponentially with increasing interval between injection of toxin and antitoxin. Similar conclusions were reached by Miles and Miles (1943), who found that mice receiving an intramuscular dose of *Cl. welchii* toxin that would kill them in 6–8 hours could be protected by an intravenous dose of 0·1 unit of antitoxin after 1 hour; after 4 hours an intravenous dose of 40 units was ineffective. Stockhusen (1936), however, records that diphtheria toxin adsorbed to washed guinea-pig organs can to some extent be dissociated from the cells by a dilute solution of antitoxin, indicating that there are various degrees of firmness in the fixation of toxin to tissues (see also Chapter 77).

The explanation of the disproportionately large doses of antitoxin required for the neutralization of established intoxications does not lie wholly in the adsorption of toxin on to susceptible tissues in such a way that antitoxin cannot neutralize it. We shall discuss in Chapter 47 the influence of the anatomical and physiological peculiarities of the site of infection on this phenomenon.

A purely antitoxic immunity affords adequate protection against such a disease as diphtheria, in which the tissue invasion is minimal and the ill effects are due almost entirely to the toxæmia. Does it afford effective protection against those bacteria that are invasive as well as toxigenic? We should expect that it would protect only against that part of the total pathological effect that is due to the action of the toxin itself. If the toxin plays any important part in the invasive process, the antitoxin might to that extent lessen the extent of infection. But we should expect modification of the infection rather than complete immunity. The available evidence is in accord with our expectations.

The presence of circulating antitoxin, active against the rash-producing toxin of the hæmolytic streptococcus, affords protection against clinical scarlet fever, that is, against the obvious effects of the toxin itself; but it does not appear to protect against the local lesion in the throat—the acute tonsillitis (Okell 1932). Again, it would seem (Burt-White,

Colebrook and others 1930, Baird and Cruickshank 1930, Stent 1930) that the presence of circulating antitoxin, as revealed by a negative Dick test in pregnant women during the later stages of gestation (see p. 1481) affords little if any protection against a severe or fatal infection with hæmolytic streptococci during the puerperium. These clinical findings are borne out by the results of experiment. Thus, Parish and Okell (1927) found that a potent antitoxic serum, which would protect rabbits against acute toxæmic death following the intravenous injection of large doses of living cultures of hæmolytic streptococci, did not prevent a fatal infection, leading to death after a week or more, associated with multiple foci of infection. Nevertheless, as reference to Chapter 66 will show, in patients with scarlet fever, antitoxic sera sometimes appear to influence the course, not only of the toxæmia, but of complications directly referable to the bacterial invasion by the *Str. pyogenes*.

Closely analogous results have been obtained in experimental staphylococcal infections in the rabbit (Burnet 1929, Burnet and Kellaway 1930, Kellaway, Burnet and Williams 1930). The potent staphylococcal toxin is neutralized, in multiple proportions, by the specific antitoxin; and a rabbit can be actively or passively immunized against the poisonous effect of a toxin-containing filtrate. But such immunized animals are still susceptible to the injection of living staphylococci and succumb to a pyæmic infection, though they survive rather longer than non-immunized controls. Later studies, however, indicate clearly that in rabbits antitoxin protects, though not completely, against bacterial invasion. Ramon and his colleagues (1936) found that intravenous virulent *Staph. aureus* did not kill rabbits with a high level of antitoxin in the serum, whereas rabbits with a low level succumbed. Kitching and Farrell (1936) observed that immunization with toxoid protected rabbits against infection, but that immunization with bacterial bodies, though it produced abundant agglutinins, was ineffective. Both Forssman (1936) and Smith (1937) demonstrated that active immunization with staphylococcal products was effective with those antigens that induced the formation of antitoxic antibodies. Downie (1937) studied active and passive immunization against living staphylococci and staphylococcal toxin, intradermally administered, and concluded that as far as rabbits were concerned, antitoxic antibodies were more beneficial than antibacterial in immunity to the bacterial infection (see also Mercier 1937, Delaunay 1938).

To speak generally, it is clear that antitoxin, by removing the burden of progressive intoxication from the tissues of the animal, may permit them to exert their antibacterial action with greater efficiency. Thus Ritossa (1937) found that human leucocytes readily ingested virulent diphtheria bacilli, but that many of them subsequently degenerated. The degeneration could be prevented, and phagocytosis improved, if antitoxin was added to the bacilli before phagocytosis. Stewart (1943) observed a similar phenomenon in guinea-pigs injected intraperitoneally with virulent *Cl. welchii*. In animals actively or passively immunized with antitoxin, there was marked intraperitoneal phagocytosis; in non-immune animals, there was little phagocytosis, though leucocytes were abundant, and the animals died of the infection.

Thus, we may say that antitoxic immunity is highly effective *so far as it goes* —much more effective, within its own sphere, than the specific antibacterial immunity discussed in the next chapter; for it is direct in its action, does not depend on the efficient functioning of a complex system of phagocytic cells, and is complete and final in its effect on the noxious agent. If the invasive power of an infecting toxigenic organism is so low that the normal antibacterial defence mechanism can be relied on to suppress it, or to hold it in check, an added antitoxic immunity will afford almost complete protection against the corresponding disease.

It will be observed that the characteristic mechanisms of antitoxic immunity, as here defined, are brought into play only against those toxins that diffuse freely from a locus of infection. Reactions between endotoxins and the corresponding

antibodies undoubtedly play a part, perhaps a large part, in infection and resistance; but only in a few instances is it possible to differentiate clearly between anti-endotoxic and antibacterial immunity. It has, for instance, been noted in Chapter 44 that some endotoxins are identical with the surface somatic antigens that determine the immunological reactions of the intact bacterial cells.

This chapter is itself a summary.

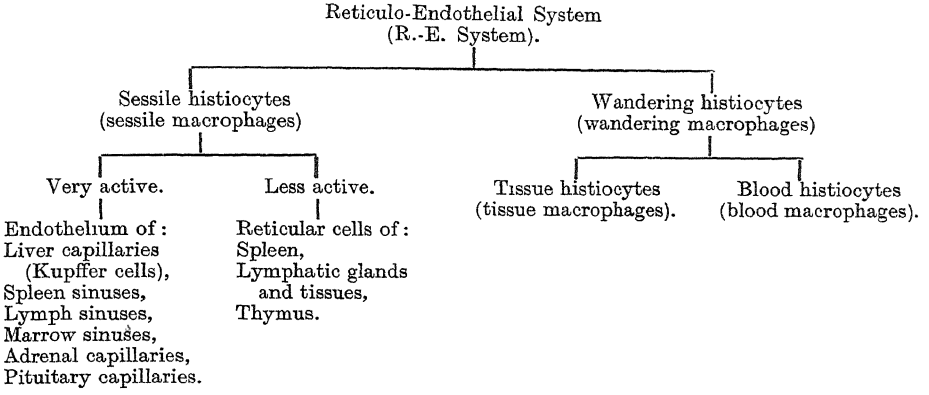
CHAPTER 47

THE MECHANISMS CONCERNED IN SPECIFIC ANTIBACTERIAL IMMUNITY

THE only sound basis for a discussion of this subject would be to treat it as a problem in comparative pathology, describing in turn the reaction to infection of unicellular organisms, of simple multicellular animals, of the invertebrates, and of the vertebrates, culminating in the mammals and man. It happens that, owing to the classical studies of Metchnikoff, our earlier knowledge of the cellular reactions involved in immunity was developed largely along these lines; and any serious student of the subject should make himself familiar with the work of Metchnikoff and his school (Metchnikoff 1901). For a review of Immunity in Invertebrates, see Huff (1940). For our present purpose, however, it will suffice to note that the mechanisms that are described in this chapter are clearly traceable, in their gradually increasing complexity, differentiation and modification, from the simplest to the most highly organized of animal hosts. In the pages immediately following we shall be concerned almost entirely with happenings in the small mammals of the laboratory; and it will be convenient to deal first with the reactions of normal animals, and then to consider how these reactions are modified by active or passive immunization.

The Reactions which follow the Intravenous Injection of Dyes or Suspensions of Inert Particles into Normal Animals.



The simplest introduction to a discussion of the mechanisms concerned in antibacterial immunity is a brief description of the way in which the living tissues deal with certain dyes and suspensions.

In pre-bacteriological days Hoffmann and von Recklinghausen (1867) and Ponfick (1869) noted that particles of carmine and vermilion, when injected intravenously into animals, were not eliminated in the urine or the bile, but were deposited in various organs such as the spleen, liver, lymph nodes and bone-marrow, where they remained recognizable for weeks. More recently, particularly within the last two decades, extensive and detailed studies have been carried out on the effects of intravital staining with a variety of dyes such as trypan blue, vital red, pyrrhol blue (isamine blue), diaminefast scarlet and benzopurpurin, or with suspensions of finely divided carbon (Indian ink) or colloidal ferric oxide (saccharated oxide of iron). An account of an investigation along these lines and a good review of the literature will be found in a series of papers by Cappell (1929, 1930).

Briefly, these studies have shown that the various dyes are stored, in the form of granules or in intracellular vacuoles, by certain cells that have a characteristic distribution throughout the body. The histologist calls these cells *histiocytes*, the immunologist knows them best by Metchnikoff's name, *macrophages*. The most active may be divided into two main types, the sessile and the wandering. The

most active of the sessile histiocytes are those found in certain specialized areas of the vascular or lymphatic endothelium—the endothelium of the liver capillaries (Kupffer cells), of the spleen sinuses, of the venous sinusoids of the bone-marrow, of the capillaries and medullary sinusoids of the adrenals, of the capillaries of the pituitary gland, and of the sinuses of the lymph glands throughout the body. Somewhat less active in this respect are the reticulocytes, which do not form a lining to blood or lymphatic channels, but are disposed about the reticulum fibres in the interstices of the tissues. The wandering histiocytes are found throughout the tissue spaces, and some of them find their way into the circulating blood, particularly into the vessels of the internal organs.

The common character of dye-storage possessed by cells of this type has led many observers, and particularly Aschoff (1924), to regard them as an integrated system of cells fulfilling a particular bodily function. Aschoff has coined for them the generic term of *reticulo-endothelial system* (R.-E. system, for short). This system, as described by him, is summarized in schematic form as follows.

The schema classifies the various cells belonging to the system, and does not necessarily represent a genealogy of the cells found in the animal body. The phylogenetic interrelations of the various types of phagocytic cell in the mammalian body is still in a controversial stage. For our purpose the R.-E. system is a functional unit consisting of cells derived from the mesenchyme, having in common a phagocytic activity (see, for example, Doan 1940); and we are particularly concerned with the more active phagocytic cells, and the sessile histiocytes of the lymph glands, liver, spleen and bone-marrow, and the wandering histiocytes in general.

As Cappell emphasizes, there is no gradual transition from the less specialized endothelium to that in which the sessile histiocytes are found. The endothelium of the lymph sinuses abruptly assumes a pronounced vital-staining capacity, in marked contrast to that of the endothelium of the afferent and efferent lymphatics; while the same contrast exists between the endothelium of the spleen sinuses, liver capillaries, etc., and the vascular endothelium in general. There is probably some degree of functional differentiation between different parts of the reticulo-endothelial system. Some histiocyte depôts may be more active in removing effete blood corpuscles or leucocytes, others in removing bacteria or smaller particles. There is also a difference between one animal species and another in the relative activity of the various depôts of sessile histiocytes. Thus the bone-marrow of the mouse is far less active than the bone-marrow of the rabbit (Cappell 1930). In birds, the mass of the reticulo-endothelial system is concentrated in the liver.

The histiocytes are not, however, the only phagocytic cells with which we are concerned. The polymorphonuclear leucocytes of the blood, although they do not take up vital stains in the same way as the cells of the reticulo-endothelial system, play an active part in removing particulate material from the circulation under certain specialized conditions.

The intervention of these cells is, for instance, brought about by the injection, directly into the blood stream, of an Indian ink suspension or of some similar material. Following such an inoculation, the polymorphonuclear cells accumulate in certain areas—most abundantly in the pulmonary capillaries, to a less extent in the veins and sinusoids of the liver, spleen and other viscera. The abundance of polymorphonuclear cells in the lungs, which may be associated with a definite leucopenia in the peripheral circulation, is so characteristic a feature of the reaction as to make it quite clear that some mechanism is at work which temporarily retains the circulating leucocytes in this particular situation. While in the lungs the polymorphonuclear cells take up a certain number of the injected carbon particles; but the degree of phagocytosis is relatively slight, and in marked contrast to the active engorgement of particles by the histiocytes of the reticulo-endothelial system (Dudgeon and Goadby 1931). In the course of a few hours the majority of the polymorphonuclear cells leave the lung capillaries. Some of them pass into the alveolar spaces, some along the lymphatics to the regional lymph glands; but the great majority appear to make their way back into the general circulation and so pass to the spleen sinuses, where they appear to be taken up by macrophages.

There is still another mechanism at work in freeing the general circulation from injected foreign particles, in which no cellular elements are primarily concerned. Many suspensions, including carmine and Indian ink, are unstable when introduced into the blood stream. The dispersed particles are rapidly agglutinated into larger masses, and these appear to be filtered off from the circulating blood, during its passage through the finer capillaries. These aggregates are themselves phagocytosed at later stages. It has been noted that the aggregates of carbon particles contain large numbers of blood-platelets (Delrez and Govaerts 1918), and their formation is associated with a definite peripheral thrombopenia (Dudgeon and Goadby 1931). Whether the platelets play any active part in the process of flocculation is, however, very doubtful. The phenomenon of aggregation—certainly in the case of bacteria and presumably in that of any particulate material—appears to be unaffected after the elimination of platelets by the injection of an antiplatelet serum (Govaerts 1921*a*, *b*, Bull and McKee 1922).

Confining ourselves for the moment to the particular case of the direct introduction of particulate matter into the blood stream, we may inquire in what ways our description needs modification or extension when our injected particles are living bacterial cells.

The Reactions which follow the Intravenous Injection of Bacteria into Normal Animals.

There is no doubt at all that the mechanism brought into play in clearing the blood stream from bacterial cells is in the main identical with that which frees it from inert particles of the same order of size (Wyssokowitch 1886, Werigo 1894, Opitz 1898, Bardach 1889, Métin 1900, Bail 1905, Bull 1914–16, Kyes 1916, Bartlett and Ozaki 1917, 1918, Wright 1927 and many others). The reticulo-endothelial cells, particularly those of the liver, spleen and bone-marrow, actively phagocytose the injected bacteria. The mechanism of aggregation, followed by the removal of the bacterial aggregates from the general circulation by their retention in the

lung capillaries, is sometimes very prominent (Bull 1914–16, Bartlett and Ozaki 1917, 1918, Wright 1927, Dudgeon and Goadby 1931). This is accompanied, as in the case of the intravenous injection of carbon particles, by an accumulation of polymorphonuclear cells in the lung capillaries, associated with a temporary peripheral leucopenia (see Levaditi 1901, Andrewes 1910). But the polymorphonuclear cells appear to play a more active part in phagocytosing bacteria than in phagocytosing carbon particles (Dudgeon and Goadby 1931). It is probable that these cells with their ingested bacteria are subsequently carried to the reticulo-endothelial depôts in the spleen, liver and elsewhere, and are there phagocytosed by the sessile histiocytes. Such wandering histiocytes as are present in the lung capillaries ingest the bacterial cells, or cell-aggregates, directly.

So far then as we can regard bacteria merely as foreign particles, our description of the reaction of the tissues to the intravenous injection of vital stains or carbon particles needs little modification. But, in fact, the bacteria we inject are alive and capable of multiplication; and it is the balance between their capacity to multiply and the capacity of the tissues to remove them that determines the fate of the animal host.

Bull (1914–16) counted the viable bacteria in the systemic blood stream of dogs and rabbits at various intervals after the intravenous inoculation of a bacterial suspension. Using pneumococci and streptococci he found that there was at first a sharp and progressive fall in the number of organisms in the circulating blood, lasting until about the 5th hour. After this there was in most cases a secondary rise, varying in degree and persistence with the virulence of the organism and the resistance of the host. With strains of low virulence the numbers then declined until the blood became sterile. Typhoid bacilli, injected directly into the blood stream, showed a similar rapid fall in numbers within a few minutes of inoculation. In one experiment they fell from 10,000,000 per ml. 1 minute after injection to 40 per ml. at the end of 15 minutes.

Wright (1927) has carried out a very detailed series of experiments on experimental pneumococcal septicæmia in the rabbit, and the following illustrative examples are taken from his paper.

TABLE 69

LIVING PNEUMOCOCCI PER ML. OF CIRCULATING BLOOD AT STATED TIMES AFTER INOCULATION OF AVIRULENT, SLIGHTLY VIRULENT, AND HIGHLY VIRULENT PNEUMOCOCCI INTO NORMAL RABBITS.

Time.	Avirulent.	Slightly Virulent.	Highly Virulent.
Immediately	8,900,000	1,030,000	1,070,000
2 hours	206	20,800	137,000
5 ,,	2	340	25,000
24 ,,	0	1,300	1,510,000
48 ,,	—	134	Dead
96 ,,	—	0	—

In Table 69 are set out the numbers of living pneumococci per ml. of circulating blood at varying intervals after the intravenous injection of (*a*) an avirulent, (*b*) a slightly virulent, and (*c*) a highly virulent strain. In Fig. 240 the same series of observations are set out in chart form, the logarithms of the numbers of pneumococci per ml. of circulating blood being plotted as ordinates against time as abscissæ. The figures need no comment. With an avirulent strain the clearance of the organisms from the blood stream is rapid and permanent. With a slightly virulent strain there is the same initial rapid clearance, so that

99·97 per cent. of the injected organisms have been removed from the blood stream by the end of the 5th hour. There is then a period during which the capacity of this strain of pneumococcus to multiply in the tissues—limited though it is—makes itself felt, and the number of viable organisms rises from 340 per ml. at the 5th hour to 1,300 per ml. at the 24th hour. But the clearing mechanism is now removing the newly generated bacterial cells at a greater rate than this particular strain can produce them. The number of organisms per ml. sinks to 134 at the 48th hour, and the blood is sterile by the 96th. The

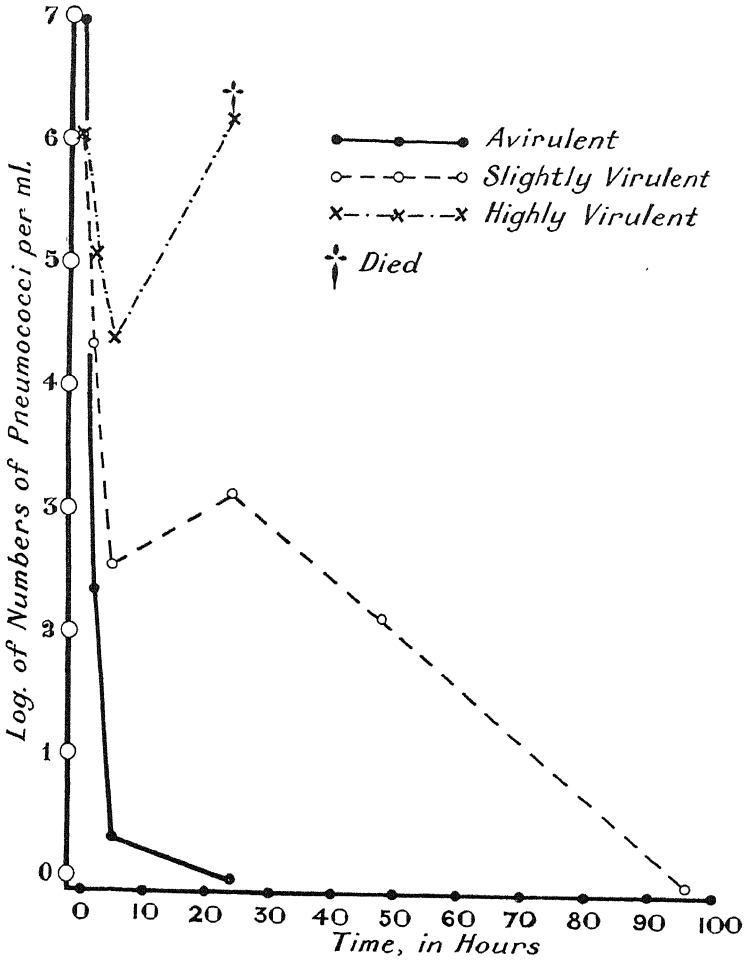


FIG. 240.

highly virulent strain is not proof against the initial action of the clearing mechanism. By the 5th hour 97·7 per cent. of the injected pneumococci have been removed from the blood stream. But when the parasite's capacity for multiplication is brought fully into play it overwhelms the defence mechanism of the host. By the 24th hour the number of pneumococci per ml. of circulating blood has risen to 1,510,000; and between the 24th and 48th hours the rabbit dies from acute pneumococcal septicæmia.

It is probable (Wright 1927) that the initial rapid clearing which follows the intra-

venous injection of a large dose of virulent pneumococci is the result of the lag phase in bacterial growth (see Chapter 4). Wright has shown that this initial clearance of virulent pneumococci can be almost eliminated by injecting a culture that is still in the logarithmic phase.

In the argument from analogy, which plays so large a part in the construction of our concepts of infection and resistance, we must be very careful to allow for the effects of our experimental technique. The reactions which we have described above are those that follow the sudden introduction into the blood stream of a relatively enormous number of bacteria—a number of the order of 1,000,000,000. Such an occurrence must be of extreme rarity in natural infection, and it is possible that some part of the mechanism we have described—for instance, the aggregation of bacterial cells and the retention of the aggregates in the lung capillaries—may have been over-emphasized by the particular experimental procedure that we have chosen to employ. In any case there seems little doubt that the most significant happenings are those that occur between the 5th and 24th hours after an intravenous inoculation, when the fate of the host is being determined by the balance between bacterial multiplication, on the one hand, and the removal of the newly produced bacterial cells on the other.

Even when the tide has for the moment turned decisively in favour of the host, it does not follow that there will be a complete sterilization of the tissues. Bacteria will have been caught up in the liver, spleen and elsewhere, and there some of them may remain alive, but relatively inactive, for considerable periods.

Our knowledge of the exact method by which bacteria are *killed* in the tissues is woefully incomplete. There is no doubt at all that the majority of the bacteria taken up by phagocytic cells are destroyed by intracellular digestion ; but the tacit assumption that a bacterium phagocytosed is, of necessity, a bacterium finally disposed of is certainly unwarranted.

The Reactions that follow the Intraperitoneal Injection of Bacteria or of Suspensions of Inert Particles into Normal Animals.

The small quantity of fluid present in the normal peritoneal cavity, or other serous sac, contains very few cells, and these consist almost entirely of mononuclears, mainly of the lymphocyte type (Dudgeon and Ross 1906, Cappell 1930, and many others).

Durham (1897), in his classical paper on the reaction to intraperitoneal infection, described the course of events that follows the injection of bacterial and other suspensions into the peritoneum of the guinea-pig. As regards the changes in the cellular contents of the exudate, there is a preliminary period lasting for about 1 hour or less during which no increase in cells can be detected. The cellular reaction, when it occurs, differs widely in degree and in character according to the kind of inoculum employed. With injections of dead bacteria, or of living strains of low virulence, there is a rapid emigration into the peritoneal cavity of polymorphonuclear leucocytes (or *microphages*, if we employ the terminology of Metchnikoff) which ingest the bacterial cells. These cells increase in number up to the 8th hour or later, and then slowly decline. As they decline, their place is taken by large mononuclear phagocytes (*macrophages*), which ingest those bacteria that still remain free in the fluid, together with many of the polymorphonuclear cells and the bacteria that they have already phagocytosed. Durham puts the duration of the whole period of peritoneal reaction, from the time of the first appearance

of the microphages to the final disappearance of the macrophages and the return to normal, as 4 to 7 days.

Although this microphage-macrophage succession may be regarded as the modal reaction in the peritoneal exudate following the injection of a bacterial suspension, it requires considerable modification in the light of subsequent studies (Dudgeon and Ross 1906, Buxton and Torrey 1906*a*, *b*, *c*, *d*, Cappell 1930). The cellular content of the exudate during the earlier hours of the reaction is by no means confined to polymorphonuclear cells, and other cells present during this period may be actively phagocytic. Cappell (1930) believes that the appearance of typical macrophages during the later stages of the reaction is due not to the emigration of fully formed cells of this type from some neighbouring depôt of histiocytes, such as the omentum, but to the gradual maturation of the small mononuclears that are present in the exudate from the earliest stages. These he regards as immature macrophages, and he believes them to be derived mainly from the small mononuclear cells that are so plentiful in the *tâches laiteuses* and adventitial sheaths of the omentum and mesenteries (see also p. 1044).

These events in the fluid exudate form only a part, perhaps only a minor part, of the general peritoneal reaction. Certain specialized regions of the peritoneal membrane, and of the tissues which are subjacent to it, play a very important rôle. Among these specialized tissues the omentum is pre-eminent (Durham 1897, Buxton and Torrey 1906*d*, Dudgeon and Ross 1906). Just as particulate material injected into the circulation tends to be aggregated into masses that are caught up in the lung capillaries, so the particles or cells in a suspension injected into the peritoneum are aggregated into masses that are deposited on the omental surface; and, just as the polymorphonuclear cells of the circulating blood tend to collect in the lung capillaries together with the aggregated particles, so such cells as are present in the peritoneal exudate tend to collect on the surface of the omentum. On this surface, and in the interstices of the underlying tissue, macrophages are normally present, especially in the milk-spots, or *tâches laiteuses*; and these cells play from the first an active part in the phagocytosis of the deposited particles or cells. Ingestion completed, these cells migrate into the deeper omental tissues, changing in shape as they do so from the spheroidal or slightly irregular form of the macrophage of the body fluids or surfaces to enormously elongated trailing cells, which make their way through the interstices of the tissues. When such cells have phagocytosed large amounts of some indigestible material, such as carbon particles, they may be detected in the tissues for periods of weeks or months. The part played by polymorphonuclear cells in the omental reaction appears to vary with different inocula. According to the observations of Buxton and Torrey, they are absent or very scanty during the first few hours or so, but they then begin to collect in increasing numbers and to play their part in the phagocytic reaction.

These reactions at the surface of the omentum, and in its interstices, are rendered doubly effective as a clearing mechanism by the movements of the omentum as a whole following the injection of a suspension of particles or bacteria into the peritoneal cavity. Disposed at first as a more or less extended fold, hanging down among the intestinal coils, it is gradually gathered up into a closely folded band, extending across the peritoneum, and carrying with it, as in a retracted net, the particles caught on its surface layers. The mechanism of these movements has been studied by Florey and Carleton (1926). They find that the omentum is totally incapable of any intrinsic movement. The movements that it undergoes are impressed on it by (*a*) posture, (*b*) the peristaltic movements of the intestines, and (*c*) the movements of the diaphragm. The retraction into a tightly gathered transverse band is due to the alteration in the character of the omental surface, and parti-

cularly to the deposition of fibrin, which causes the omental folds that are brought into apposition to adhere to one another, instead of extending again in response to the next passive movement.

The reaction that follows an intraperitoneal injection is not, however, limited to the peritoneal cavity. Indeed, it spreads beyond it with surprising rapidity.

Muscatello (1895) injected carmine suspensions into the peritoneum, killed the inoculated animals after various intervals, and studied the distribution of the dye. Within 1–2 hours he found particles of carmine in the liver and spleen. Similar particles, in smaller numbers, were found in the lungs, pancreas and testis. Durham (1897) noted the rapid passage of bacteria from the peritoneal cavity to the blood stream, and concluded that the most important route of transit was *via* the diaphragmatic lymphatics, the anterior mediastinal glands and the right lymphatic duct. The importance of the diaphragmatic route was also noted by Dudgeon and Ross, and the correctness of Durham's conclusions has been confirmed by many subsequent observers, notably in the careful studies of Buxton and his co-workers, and in the more recent studies of Bolton (1921). Buxton and Torrey (1906*b*) found that, almost immediately after the intraperitoneal injection of an Indian-ink suspension, there was a rush of carbon particles into and through the lymphatics of the diaphragm. Thence they passed rapidly through the anterior mediastinal lymphatics and the corresponding lymph glands, reaching the blood stream within a very few minutes. During the earliest stages of this transit there was very little evidence of phagocytosis in the mediastinal glands or elsewhere; but, as time passed, an increasing number of carbon particles were found within the histiocytes of the lymph nodes.

In other experiments (Buxton 1906, Buxton and Torrey 1906*a*) the fate of living typhoid bacilli, injected intraperitoneally into rabbits, was followed by quantitative plating methods. The living bacilli passed into the general circulation almost immediately; and their numbers per ml. of circulating blood reached a maximum after about an hour. After this there was a rapid decrease, and few bacilli could be recovered from the blood after about the 6th hour. When suspensions of liver and spleen tissue were plated it was found that there was a rapid accumulation of bacilli in these organs, and particularly in the liver, within a few minutes after an intraperitoneal injection. There was then a transitory decrease in the numbers of viable organisms, followed by a secondary increase lasting from the 2nd to the 6th hour, *i.e.*, the bacilli were increasing in the liver and the spleen while they were decreasing in the blood. After about the 6th hour there was a general decrease, lasting for several days, and more rapid in the liver than in the spleen. When animals were killed 4 days after injection viable bacilli were still recovered from the liver, though in small numbers; larger numbers were recovered from the spleen, and very large numbers from the mediastinal glands. Many observations on laboratory animals have shown that living bacilli may be recovered from the spleen weeks or months after experimental infection (Topley and Wilson 1923, Price-Jones 1927).

It may be noted that the rapid transit of particles or bacteria from the peritoneum to the blood stream is almost certainly the result of the mechanical pumping action of the rise and fall of the diaphragm in breathing. This is probably assisted by a special arrangement of the endothelial cells of the peritoneal membrane covering the diaphragm, which provides for a rapid passage of particles to the underlying lymphatics (Florey 1927).

The Reactions that follow the Injection of Bacteria or Inert Particles into the tissues of a Normal Animal.

By injecting bacteria into the blood stream or the peritoneal cavity, we are in a sense by-passing a stage that must occur in the majority of natural infections. After penetrating the epithelial layer, whether it be of skin, respiratory, alimentary

or genital tract, the particulate infecting agent comes to lie in the intercellular spaces of subepithelial tissues, or, as we saw in Chapter 44, it may rapidly penetrate into a particular type of cell. The usual sequence of events, the induction of an inflammatory process by the toxins of the bacterium, the mobilization of microphages and macrophages, exudation and in some cases the formation of fibrin clots, may result in a localization of the invading organisms, and their gradual destruction by the antibacterial action of certain fluids and cells of the host. Sometimes the local defences are overcome, and the bacteria are disseminated *via* the lymphatic capillaries to the lymph nodes, and, if they are not held there, from thence to the blood stream, with the establishment of a generalized and perhaps fatal disease. But though localization of the disease process may clearly be a reaction tending to promote the survival of the animal infected, localization of the primary infecting dose is not necessarily so. It is arguable that immediate dissemination of the infecting bacteria, so that they are " diluted " in the healthy antibacterial tissues of the host, may ensure their destruction more certainly than their localization in a site where perhaps they may multiply and ripen into a focus of infective particles that will later be disseminated with fatal results. The number of bacteria that get into the tissues at the start of a natural infection is likely in most cases to be small, and it is to be noted that when small inocula are injected experimentally, a given dose of bacteria may be less noxious when " diluted " directly in the blood stream, than as an injection into the tissues.

Lange and Gutdeutsch (1928) found that pneumococci, streptococci and pasteurellæ were more fatal to mice when injected intraperitoneally than when injected subcutaneously or intravenously, and that the subcutaneous was rather more fatal than the intravenous route. In the case of *Erysipelothrix rhusiopathiæ*, the bacillus causing swine erysipelas and mouse septicæmia, the subcutaneous route of injection was found to be more fatal than the intraperitoneal or intravenous. According to Sobernheim and Murata (1924), the dose of *B. anthracis* required to kill a guinea-pig after intravenous or intraperitoneal inoculation is about ten times the dose that will produce a fatal infection when injected by the subcutaneous or intracutaneous routes. Whether or not it is beneficial that particles should reach the blood stream as soon as possible, or be held locally, we must examine the factors likely to promote both events. At the outset we may note that the passage of particles from the tissues directly through the capillary endothelium appears to be unlikely, except in rare cases of gross mechanical trauma to the capillaries, and perhaps in infections with organisms that proliferate selectively in the endothelium itself. As a rule both particles and bacteria reach the circulation by a less immediate route.

The Permeability of Blood and Lymph Capillaries to Foreign Matter.—Underlying the various epithelial surfaces of the body there is an extensive anastomotic network of blood capillaries and lymphatic channels. The two networks, with rare exceptions, constitute independent systems, each lined by a continuous sheet of endothelial cells. The lymphatic network drains into the afferent lymphatic channels, which in turn lead to a lymph node (Drinker and Yoffey 1941). In normal tissues, excepting the liver, the permeability of both capillary and lymphatic endothelium is poor. Substances of low molecular weight only are absorbed from the tissue by the capillaries. For instance, Rous and his colleagues (Rous, Gilding and Smith 1930, Smith and Rous 1931*a*, *b*, Rous and Smith 1931) showed that certain dyes passed directly into the venous portion of a capillary

loop. Cobra venom, of molecular weight 5,000, is absorbed directly into the blood stream, but diphtheria and tetanus toxins, of molecular weights greater than 20,000, are not (Barnes and Trueta 1941). Serum proteins do not pass directly into the blood stream from the tissues (Starling 1895–96). The permeability of the blood capillaries increases greatly with trauma, and under the influence of various noxious substances. It does not appear that the passage into the blood stream of particles of bacterial dimensions is facilitated in these circumstances; though Tuttle and Cannon (1935) obtained some evidence that virulent streptococci passed directly into the blood stream after their introduction into the lung alveoli of dogs. The lymphatics, on the other hand, readily become permeable to large molecules and small particles introduced directly into the intercellular tissue spaces, whether they are, for example, inert particles, red blood cells or bacterial in nature (see, for instance, Cappell 1929, Batchelder, Field and Drinker 1931, McMaster and Hudack 1934, Field and Drinker 1936, Schulz, Warren and Drinker 1938, Barnes and Trueta 1941). We have already noted the speed with which bacteria reach the thoracic duct *via* the lymphatics, from the peritoneal cavity, etc. These facts suggest that in areas which, like the skin and subepithelial tissues of the respiratory and alimentary tracts, are liberally supplied with lymphatics, invading bacteria in many cases are rapidly carried to the lymph nodes draining the site of invasion.

The Filtering Action of Lymph Nodes.—As Drinker, Field and Ward (1934) showed, hæmolytic streptococci or particles of india ink introduced into an afferent lymph channel are to a large extent removed from the lymph during its passage through a lymph node. The filtration appears to depend mainly on the complex ramifications of the channels in the node, and to a lesser extent on the removal of particles by phagocytic cells lining the sinusoids of the node. The filtration, however, is by no means complete. Schulz, Warren and Drinker (1938) instilled virulent Type III pneumococci into the nose of rabbits, and recovered cocci from the vessels draining the superior deep cervical node within one hour of the instillation; non-virulent organisms, on the other hand, did not appear in the efferent lymph. Where lymph has to traverse several nodes in its passage to the thoracic duct filtration may be very efficient. Thus Drinker, Field and Ward (1934) passed large numbers of streptococci through the popliteal and iliac lymph nodes of a dog; 14 ml. of a culture containing at least 250×10^6 organisms per ml. were perfused in 88 minutes; at the end of 56 minutes, 1 ml. quantities of thoracic lymph were sterile, and even after 88 minutes' perfusion, the number of streptococci per ml. was only of the order of 100.

It seems probable that the nature of the particle affects the efficiency of filtration. Thus, Yoffey and Sullivan (1939) found that vaccinia virus instilled into the nose of rabbits appeared in the thoracic duct after a delay of twelve hours, and continued to do so for seven days after instillation. It is not known whether this represented a ready passage of virus through the node, or its retention and multiplication in the tissues of the node, with subsequent discharge into the efferent lymphatics.

As we have seen, the introduction of infective particles into the tissues is usually followed by varying degrees of local inflammatory reaction, and it is pertinent to inquire how far these affect the fate of the particles. Our knowledge of the value of the inflammatory reaction as a defence against infection is still very incomplete. In recent years, however, interest in this aspect of inflammation has been stimulated by extensive analyses of the inflammatory processes made by Menkin in the United States. Briefly, Menkin's view of the process of acute inflammation is as follows.

At the site in which inflammation develops, three substances are liberated from the tissues: leukotaxine, a crystalline polypeptide that increases the permeability of the blood capillaries and is positively chemiotactic, thus attracting polymorphonuclear cells to the inflamed area (Menkin 1936, 1938); a pseudoglobulin which acts on the bone marrow and induces a polymorphonuclear leucocytosis (Menkin 1940*a*, *b*, Menkin and Kadish 1942); and a toxic euglobulin called "necrosin" (see Chapter 44) which is responsible for the necrosis of tissue in the inflammatory area (Menkin 1943*a*). According to Menkin, predominance of any one type of phagocyte at a given stage of the inflammatory process is a function of the metabolic state of the inflamed region. In the early stages, the pH is 7·0 or more, and polymorphonuclear cells predominate; in later stages, owing to the breakdown of carbohydrate in the area, a lactic acidosis occurs, and the resultant fall in pH leads to the appearance of macrophages (Menkin and Warner 1937, Menkin 1943*b*).

Apart from the necrotic effect of necrosin, each of these phenomena can be said to have survival value for an animal attacked locally by an infective parasite. Through the capillary walls made permeable by leukotoxine come phagocytes, and an exudate containing antibodies, other antibacterial substances and fibrinogen. The coagulation of the fibrinogen in this exudate leads to the deposition of a fibrin meshwork in the intercellular spaces of the injured tissues. The protein content of lymph will rise, since under the influence of leukotaxine the lymphatic endothelium will have become permeable to the exuded proteins, and under the toxic action of the invading bacteria the lymph will clot in the lymphatic channels. In favourable circumstances, therefore, the intercellular dissemination of the infective material will be hindered by the fibrin deposit in the tissues, and dissemination along the lymph channels by the intralymphatic clots. This clotting process constitutes Menkin's "lymphatic blockade" whereby irritant material is fixed and held at the site of inflammation. If the irritant is sufficiently strong, "fixation" may even precede the diapedesis of leucocytes. According to Menkin, bacteria like *Staph. aureus* stimulate an early formation of a lymphatic blockade, and hence tend to be confined in local abscesses; *Str. pyogenes*, on the other hand, induces a late fixation reaction, and is conspicuously invasive.

The presence of leukotaxine-like polypeptides in the breakdown products of tissue proteins has been demonstrated by Duthie and Chain (1939), and many of the experimental phenomena upon which Menkin bases his hypothesis of inflammatory fixation have been reproduced by other workers, though neither Steinberg and Dietz (1938) nor Lurie (1939) could find any constant association between pH and the predominating type of phagocyte in inflammatory processes. It is probable that a number of factors, including the type of parasite, determine the cellular response, even in the early stages of infective inflammation (see, for example, Gins, Kroemer and Link 1938).

We are chiefly concerned here with the hypothesis of the lymphatic blockade as a defence against bacterial invasion. The chief objection to the hypothesis is the difficulty of demonstrating fibrin deposits and lymphatic thrombi at the *periphery* of inflamed regions, that is, in the region where they are likely to be effective as a barrier against the spread of infection. Rich (1936) points out that acute inflammatory processes induce an increased, not a decreased, flow of lymph from the injured part (see Field, Drinker and White 1932, Hudack and McMaster 1933), and suggests that foreign substances, including bacteria, are "fixed" in inflamed areas by adsorption to proteins, and by precipitation or other physico-chemical change in the lesion (see also Blalock and Burwell 1935–36); and the work of Miller (1938) on the adsorption of a variety of substances, including bacterial suspensions, from regions of inflammation in rabbits,

makes it clear that absorption depends largely on the nature of the substance absorbed. Miles and Miles (1943) attribute the apparent fixation of substances in the inflammatory lesion to an accumulation of exudate in the tissues to such a degree that the existing lymphatic system can drain away only a small fraction during the period of experimental observation, with the result that any foreign material diluted in the exudate appears also to pass slowly from the lesion.

We should at this point emphasize that the term "fixation" is also used for two phenomena that are distinct from the fixation discussed above. The first concerns the localization of a blood-borne infective agent in the tissues, with the formation of a local lesion. The mechanism of this fixation, as the review of Burrows (1932) shows, is the escape of the infective material through capillary endothelium, the site of escape in most cases being determined by injury to the vessel wall. The fate of the material from this point will be determined by the factors we have already discussed. Another kind of fixation occurs in the later stages of a local infection, in the sense that the whole infected region is walled off from the rest of the body by the cellular reaction. In this case we are dealing with localization of an established *lesion*, a process which is conveniently distinguished from that we have discussed above, which is the localization of infective material soon after its introduction.

It should be noted that lymphatic circulation is largely dependent on active movement of the animal body (see Drinker and Yoffey 1941), and in the quiescent animal, on the movements transmitted through the tissues by the pulsating blood vessels (Parsons and McMaster 1938). It follows, as Barnes and Trueta (1941) have demonstrated, that the complete immobilization of a limb in plaster will greatly retard the adsorption by the lymphatics of large particles, and of substances of high molecular weight, injected into the limb.

To summarize, it is frankly impossible at present to forecast the fate of infective particles introduced into the tissues—whether they will be immobilized or carried *via* the lymphatic system to the blood. Nor can we predict which of the two results would be more effective in destroying the infective agent. Clearly both local and systemic defence mechanisms are highly effective in certain circumstances. In our opinion the known facts are inadequate for a generalization like that of Menkin on the rôle of inflammation in immunity, though the phenomena he has described are manifestly of first importance.

The Reactions that follow the Administration of Bacteria or Inert Pathogenic Particles to Normal Animals by the Respiratory Tract and by Mouth.

Our studies of the reactions following the injection of material into the tissues indicate that in most cases particles over a certain size gain access to the lymphatics, and if a lymph flow is established, rapidly reach the lymph nodes. The extensive lymphatic system of the skin is protected by a relatively thick and impermeable dermis; the equally extensive submucous lymphatic systems of the respiratory and alimentary tracts are covered by a much more penetrable mucosa.

Particles as large as globulin molecules readily penetrate the nasal mucosa and rapidly reach the lymphatics (Drinker and Yoffey 1941). Few observations have been made on the fate of viruses and bacteria in the nose. As we have seen (Yoffey and Sullivan 1939), vaccinia virus did not appear in the lymphatics until 12 hours after its introduction into the rabbit's nose, suggesting that multiplication in or on the mucosa preceded its penetration. Yoffey and Drinker (1939) could find no evidence of the lymphatic penetration by the poliomyelitis virus (see Chapter 87). Schulz, Warren and Drinker (1938)

demonstrated a ready penetration of the lymphatics, both of the nose and the trachea, by virulent pneumococci.

We shall discuss the reactions of the alveolar tissues of the lung to bacterial invasion in Chapter 74, in connection with the pathogenesis of pneumococcal pneumonia. With regard to infections by the mouth Ørskov and his colleagues (Ørskov, Jensen and Kobayashi 1928, Ørskov and Moltke 1928, Ørskov and Lassen 1930), extending the observations of Müller (1912), have recorded a series of experiments in which they fed mice with *Salm. typhi-murium* and allied strains of the *Salmonella* group by dropping measured amounts of a broth culture, or of a saline suspension, into the open mouth. The animals so treated were killed after intervals varying from a few hours to a month or more, and cultures were prepared from the blood, liver, spleen, mesenteric glands, the small intestine at different levels, and certain other situations. In this way it was possible to follow the spread of infection throughout the body. These observations are of particular interest because they are concerned with a natural disease of mice, and because the portal of entry is that by which the parasite gains access to its host in the natural spread of the disease.

It would seem that the bacilli, when they gain access to the body by the mouth, fail to establish any immediate foothold in the intestine, and for the most part rapidly succumb. A certain number, however, enter the tissues from the alimentary tract and are carried to the mesenteric lymph glands. Later they enter the blood stream, probably *via* the thoracic duct, but are rapidly removed from the circulation by the reticulo-endothelial cells, particularly those of the liver and the spleen. During this phase the blood taken from the heart is sterile, and *Salm. typhi-murium* cannot usually be recovered from the intestine; while the liver, spleen and mesenteric glands show its presence in increasing numbers. In many animals this stage is followed by a secondary bacteræmia, which increases in intensity until the animal succumbs. The intestine, which as stated above is rapidly freed from the invading bacteria during the primary stage of the infection, becomes secondarily infected during its later stages, probably by way of the bile-duct.

A similar series of experiments were carried out using *Salm. paratyphi B* as the infecting agent—an organism closely related to *Salm. typhi-murium*, but far less pathogenic for the mouse. The same rapid disappearance from the intestine was noted, and the same localization in the lymphatic glands; but in this case there appeared to be no tendency for the infection to spread beyond this primary focus, though the bacilli might persist in the mesenteric glands for weeks or months. A relatively avirulent variant of *Salm. typhi-murium* behaved in the same way as *Salm. paratyphi B*.

Bactericidal and Bacteriolytic Reactions.

It is very difficult to assess with any accuracy the part played by the lytic action of complement on sensitized bacterial cells. There is little doubt that this purely humoral effect is much less important than was at one time supposed, but it is certainly operative to some degree with certain organisms and under certain conditions.

Thus, apart from Pfeiffer's classical experiments with *V. choleræ*, Buxton and Torrey (1906*d*) note that many of the typhoid bacilli that collect on the surface of the omentum after an intraperitoneal inoculation are destroyed by extracellular lysis instead of being ingested by macrophages, and many workers have recorded analogous observations. In the case of Gram-positive organisms, such as pneumococci or streptococci, it would seem, however, that this purely humoral mechanism plays no part.

THE REACTION OF ACTIVELY IMMUNIZED ANIMALS AS COMPARED WITH THAT OF NORMAL ANIMALS

We have so far been concerned only with the reaction of normal animals to bacteria of varying virulence ; and we have seen that the normal clearing mechanism, while highly effective against a strain that has little capacity for multiplication within the tissues, may be overwhelmed by a more virulent strain that is capable of establishing multiple or extensive foci of active infection from which the circulation is continuously flooded.

So far as this particular mechanism is concerned, we can summarize the difference between an actively immunized and a normal animal very briefly, by saying that an immunized animal behaves towards a virulent strain of a particular pathogenic bacterium in the same way as a normal animal behaves towards an avirulent, or

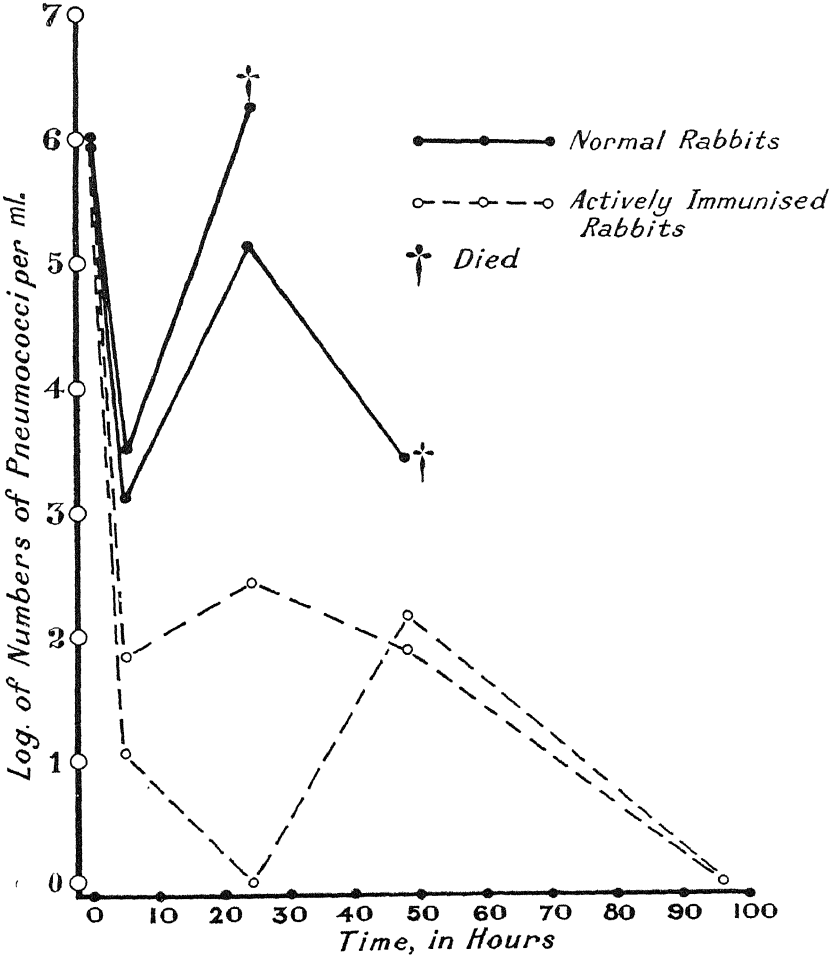

FIG. 241.

slightly virulent, strain of the same bacterial species. Without any attempt to recapitulate in detail, we may quote a few illustrative examples.

Wright (1927) studied the response, to the intravenous injection of virulent pneumococci, of rabbits that had been immunized by the injection, at various intervals before the test inoculation, of a killed culture of the same strain. Table 70 and Fig. 241 show the results obtained in two rabbits that had been immunized 3 months previously, and in two normal controls injected with the same dose of the same living culture. Comparison with Table 69 and Fig. 240 will show that the immunized rabbits dealt with the highly virulent culture in the same way as the normal rabbit dealt with the slightly virulent strain.

TABLE 70

SHOWING THE NUMBER OF PNEUMOCOCCI PER ML. OF CIRCULATING BLOOD AT VARIOUS TIMES AFTER INOCULATION OF A VIRULENT STRAIN INTO NORMAL AND INTO ACTIVELY IMMUNIZED RABBITS.

Time after Injection.	Normal.		Immunized.	
	Rabbit 247.	Rabbit 248.	Rabbit 299	Rabbit 300
Immediately	870,000	1,100,000	1,000,000	1,000,000
5 hours	1,300	3,300	12	68
24 ,,	142,000	1,953,000	0	289
48 ,,	2,800	Innumerable	149	79
96 ,,	Dead	Dead	0	0

The phagocytic reactions that we have described are illustrated in Figs. 242, 243, 244, and 245, for which we are indebted to the late Professor H. D. Wright.

The reaction in the lung capillaries in these immunized animals is illustrated by the following figures (Wright 1927) obtained from a film preparation.

Total number of pneumococci seen	893
Phagocytosed by polymorphonuclear cells	297
Phagocytosed by mononuclear cells	340
Total phagocytosed	637
Total outside phagocytes	256
In unphagocytosed aggregates associated with platelets	206
In free aggregates	53

The results that have been obtained when immunized animals have been injected with virulent bacteria by other routes—by intraperitoneal or subcutaneous injection or by the mouth—are in entire conformity with those described above. An immunized animal reacts to a highly virulent bacterium as does a normal animal to one of lower virulence. The exact degree of difference in behaviour depends on the grade of immunity that has been established.

We may cite as further illustrative examples of the reactions of normal and immune animals the studies of Angevine (1936) on intradermal infections by virulent streptococci and the detailed studies of Jawetz and Meyer (1944*a*, *b*) on the reactions of the guinea-pig to infection by plague bacilli.

The immunity with which we are here concerned is, it should be noted, strictly specific. The influence of non-specific factors on immunity is considered in Chapter 52.

The Passive Transference of Antibacterial Immunity.—The increased resistance that an actively immunized animal enjoys in virtue of the increased efficiency of the defence mechanism considered above can be passively transferred from an immunized to a normal animal by injecting into the second the blood serum of the first.

FIG. 242.

Showing phagocytosis of pneumococci by macrophages in the liver of an immunized rabbit.

FIG. 245.

Lung of an immunized rabbit, showing phagocytosis of pneumococci in capillaries of alveolar walls.

FIG. 243.

Showing phagocytosis of pneumococci by the Kupffer cells, from the liver of an immunized rabbit.

FIG. 244.

Blood from the liver of an immunized rabbit, showing phagocytosis of pneumococci.

It follows that we must regard the mechanism by which virulent bacteria are disposed of when once they have gained access to the tissues of an immunized animal as involving an integrated system of cellular reactions conditioned by the presence of specific antibodies in the blood or tissue fluids.

Again, a few illustrative examples will suffice.

Bull (1915*a*, *b*) found that, in a rabbit in which a bacteræmia had been established by the intravenous injection of pneumococci, the bacteria were removed from the circulation within about 15 minutes after the intravenous injection of 0·2–0·5 ml. of antipneumococcus serum per kilo-body-weight of the rabbit.

Wright (1927) showed that the clearing mechanism of a normal rabbit could be rendered highly effective against virulent pneumococci by the intravenous injection of the serum of an actively immunized animal. The results of one such experiment are set out in Table 71 and Fig. 246. The two passively immunized rabbits received 1 ml. respectively of the serum of an actively immunized rabbit 1 hour before the test dose of culture. It will be noted that the normal animal died between the 5th and 24th hours, so that the expected secondary rise in the number of bacteria was not observed.

96 „	—	0	0

Manwaring and Coe (1914) perfused a normal liver with a dilute suspension of pneumococci, with and without the addition of an antipneumococcal serum, and found that the retention of pneumococci within the liver capillaries was very marked in the former case, but very slight in the latter.

There are many earlier observations of an analogous kind.

Bordet (1897) showed that an antistreptococcal serum would protect a guinea-pig against the intraperitoneal injection of a lethal dose of living streptococci. By withdrawing samples of the peritoneal exudate at various intervals after the inoculation, he was able to show that the recovery of the passively immunized animal was associated with a greatly increased degree of phagocytosis, mainly by the polymorphonuclear cells. By a very ingenious experiment he demonstrated that the relatively slight degree of phagocytosis in the peritoneal exudate of the normal animal could not be ascribed to an absence of activity on the part of the leucocytes. If a suspension of *Proteus* bacilli were injected into the peritoneum of a normal guinea-pig at a time when virulent streptococci were multiplying actively therein without undergoing any considerable degree of phagocytosis, the leucocytes at once ingested the *Proteus* bacilli in enormous numbers.

Pfeiffer and his colleagues (Pfeiffer 1893*a*, *b*, 1894*a*, *b*, 1895, Pfeiffer and Issaeff 1894, Issaeff 1894) showed that an anticholera serum would protect a guinea-pig against the intraperitoneal injection of living cholera vibrios; but in this instance the protective effect would appear to depend mainly on a lysis of the vibrios, brought about by the combined action of antibody and complement.

It has, then, been shown quite clearly that specific antibodies play an important rôle in antibacterial immunity. Are they always concerned, or is there some other defence mechanism of the tissues that functions independently of them ?

The evidence at present available does not allow us to give any decisive answer to this question ; and reference to the literature shows a wide divergence between the tentative conclusions sponsored by different observers. One reason for this is

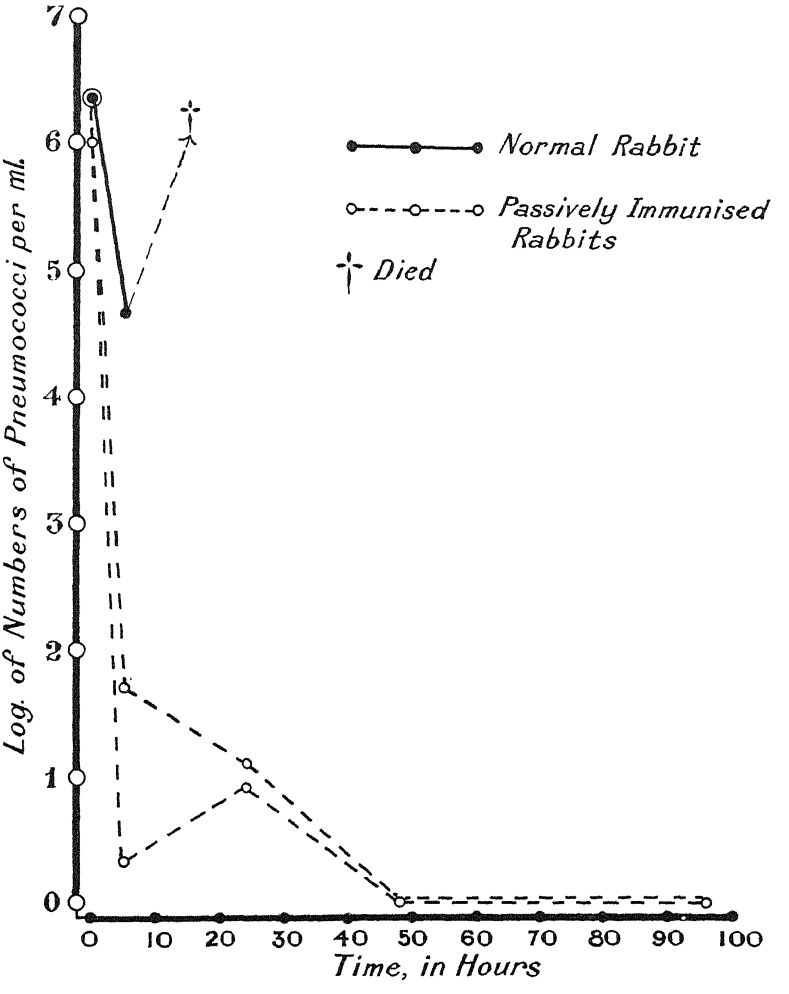

FIG. 246.

that the point at issue has not always been clearly defined. Sometimes the problem actually submitted to experimental study has been the correlation between resistance to a particular bacterium and the presence of the corresponding antibodies in the circulating blood. But we shall see, when studying anaphylaxis, that specific antibodies readily become fixed to tissue cells ; so that the demonstration of immunity in the absence of circulating antibodies, or a failure to find any correlation

between antibody titre and degree of resistance, cannot be accepted as satisfactory evidence that specific antibodies are not involved.

As an illustrative example of the relations that have been found to hold in experiments of this kind we may refer again to the careful studies of Wright (1927).

In these experiments, a large series of rabbits were immunized by a single intravenous inoculation of killed culture and were tested at various intervals thereafter by determining the rate at which virulent pneumococci disappeared from the blood stream, after the intravenous injection of 1 ml. of living culture. The results suggested that there was a slight, but definite, improvement in the clearing capacity within a few hours. This became well established on the 3rd day, was still marked at the end of a month, and might persist for 3 to 6 months, though in diminishing degree. The serum of many of these rabbits was tested for the presence of agglutinins, opsonins, and precipitins. It was found that the production of these antibodies was inconstant, and that the times of their appearance and disappearance in the blood in no way corresponded to the duration of the improved clearing capacity. In many cases no antibodies were ever demonstrable, although the rabbit showed a well-marked clearing reaction. In others, agglutinins appeared to low titre on the 4th day, increased in amount to the 7th or 10th day, and disappeared by the end of the 3rd week. Thus they first appeared after the increased clearing capacity had become well established, and vanished while it was still present in a marked degree. In connection with these experiments Wright also determined the inhibiting action of whole blood (heparinized) on the growth of pneumococci, using a modification of the methods employed by earlier workers in determining the bactericidal action of whole blood on this organism. He found that the results of this *in vitro* test were far more closely correlated with the clearing capacity of the rabbits, and with the power of their serum to confer this clearing capacity on normal rabbits, than were the results obtained by agglutination or precipitin reactions.

A protocol, taken from his paper, and slightly modified in form, affords a clear illustration of the general type of his results. (Table 72.)

TABLE 72

48 ,, . . .	134	0	0	0	0	Dead	Dead
96 ,, . . .	0						

The lack of correspondence between the presence of agglutinins and precipitins on the one hand, and clearing capacity on the other, is obvious; but the association between the growth-inhibitory action of the whole blood and the clearing capacity is very close. Similarly, those rabbits which are able to remove pneumococci rapidly and completely from

their own circulating blood are in a position to confer a similar ability on normal rabbits, by the transference to the latter of a relatively small proportion of their blood serum. The correspondence, in this case, is not absolute; but the association is well-marked.

It should, perhaps, be noted that other workers have reported the occurrence of an effective active immunity in the entire absence of circulating antibodies, as judged by all available tests, including the bactericidal power of the whole blood (see, for instance, Teale 1935).

Evidence of an essentially different kind has sometimes been appealed to in the discussion of this problem. It has been pointed out that there may be little if any correspondence between the protective power of an antiserum and its antibody content as determined by agglutination, or other *in vitro* tests (see, for instance, Wadsworth 1917, Avery *et al.* 1917). So far as this is so, it is clearly not an argument in favour of a tissue immunity as against an immunity depending on humoral antibodies—the passive transference of protection is proof enough that some humoral factor is concerned. The most that can be concluded from such observations is that the protective power of the serum is not determined by the particular antibodies measured by the *in vitro* tests. The force of most arguments of this kind has been greatly weakened during recent years by the demonstration that antibacterial immunity is dependent on the antibodies acting on particular antigenic components of the bacterial cell, while other antibodies, though giving agglutination or precipitation *in vitro*, may have no protective effect *in vivo* (see below). It has been shown too that many of the quantitative methods used by the earlier workers were very ill-adapted for the accurate assay of the antibodies concerned; and the employment of a more adequate technique has resulted, in many cases, in the demonstration of a close correspondence between the protective power of a serum and its content in a particular antibody (see Smith 1932).

As an example of an acquired cellular immunity in which the participation of antibodies has been excluded as rigorously as experimental conditions permit, we may cite the recent experiments of Lurie (1942), who injected tubercle bacilli into normal and immune rabbits, and two days later removed specimens of tissue, from which he obtained suspensions of mononuclear phagocytes containing ingested tubercle bacilli. These were injected into the anterior chamber of the eye of normal rabbits, " immune " cells into one eye, " normal " cells into the other. After 10–14 days " normal " cells had proliferated, and the chamber contained large numbers of intracellular and extracellular tubercle bacilli; " immune " cells had not proliferated and only a few degenerate bacilli were seen, mostly intracellular. Viable counts of the contents of the anterior chamber confirmed the inference that the " immune " cells inhibited the growth of tubercle bacilli. It is not, however, clear how far the increased immunity was specific for tubercle bacilli. For example, in earlier studies Lurie (1939) showed that macrophages from tubercle-immune animals were more actively phagocytic *in vitro* than those from normal animals, but that the activity was displayed, not only towards tubercle bacilli, but towards inert particles and other bacteria.

Perhaps the strongest argument in favour of the essential rôle of the serum antibodies in antibacterial immunity is the fact that such immunity is specific. It is true that a non-specific active immunity can sometimes be induced; but it is almost always of the relatively trivial and transient type described in Chapter 52. Effective and durable active immunity is usually narrowly specific; and in many cases we can identify the particular antigenic component, or components, on which it depends. If there is an immunity that has nothing to do with antibody formation, then we must invoke an additional specific mechanism, in which the same antigenic

components are in some way involved. There is nothing very unlikely in such an assumption, and it may well prove to be correct; but it will accord with the sound principle of economy of hypothesis, to reserve judgment pending the accumulation of further evidence.

The Dependence of Effective Antibacterial Immunity upon Particular Antibodies.

On which of the various serum antibodies does antibacterial immunity depend? This question was answered, in respect of one particular infection, long before anyone realized that it had been asked. Neufeld and Händel (1909), in their classical paper on the testing of antipneumococcal sera, first showed the existence of different serological types of pneumococci by noting that a given serum would protect a mouse against one strain of pneumococcus but not against another.

The demonstration of the presence of two separable antigenic components in the pneumococcal cell—the type-specific polysaccharide and the non-specific nucleo-protein—afforded an obvious opportunity of approaching this problem along more satisfying lines; and the results obtained were unequivocal. The antibody corresponding to the polysaccharide hapten was found to have a high protective value: the antibody corresponding to the nucleo-protein antigen had little, if any, protective effect (Avery and Morgan 1925, Avery and Neill 1925). A decisive demonstration of the protective action of the antibody acting on the specific polysaccharide, in the absence of antibodies acting on any other constituent or product of the pneumococcal cell, was more recently recorded by Avery and Goebel (1931). They prepared a synthetic antigen by obtaining purified polysaccharide from a culture of Type III pneumococcus and linking it to horse globulin, and with this antigen they immunized rabbits. The antisera so obtained protected mice against Type III pneumococci, but not against Type I or Type II pneumococci.

In this connection an observation of considerable interest was made by Sugg, Richardson and Neill (1929). It was found that a particular variety of yeast contained the specific polysaccharide component of the Type II pneumococcus. Vaccination of mice with a heated suspension of this yeast significantly increased their resistance to Type II pneumococcus, but not to Type I or Type III.

Goebel (1939, 1940) succeeded in demonstrating an even more precise relationship between specific immunity and the chemical structure of the major pneumococcal antigen. He prepared azo-protein antigens containing the glucoside of cellobiuronic acid, an acid known to be a constituent of Type III and Type VIII pneumococcal polysaccharides, and was able to protect mice against Type III and Type VIII infections by treatment with antisera from rabbits immunized with the azo-protein. In the same way, antibodies to antigens containing the glucosides of synthetic gentiobiuronic and glucuronic acids protected mice against Type II pneumococcal infection.

The predominating rôle of antibody to polysaccharide in type-specific immunity to pneumococcal infections is well established, and it is of interest to note that where the main antigen of a pneumococcal type is complex, the most solid immunity is achieved when antibodies to all the components are present. Kauffmann, Mørch and Schmith (1940) separated the Type VII pneumococcus into four sub-types distinguished by different combinations of eight antigenic components, *a* to *h*. Björneboe (1940) was able to prepare sera specific for some of the separate components, and showed that full protection of mice against Type VII (containing $a + b$) and Type VIIA (containing $a + b + c$) was obtained only when the animals received mixtures containing the full quota of corresponding antibodies, *i.e.*, anti-a + anti-b, and anti-a + anti-b + anti-c, respectively.

Certain workers, notably Day (1933, 1934) and Harley (1935), describe an acid-extractable, species-specific, immunizing antigen in pneumococci. Downie (1938) was unable to find an antigen of this character in pneumococci, though he described an antiprotein antibody with some protective power (see Chapter 54). Street (1942), however, reports that prolonged immunization of rabbits with an R Type II pneumococcus induced a

species-specific antibody that protected the immune animal against intrapleural infections of virulent Type I pneumococci. Its chief effect appeared to be opsonic, particularly in respect of the macrophages.

Julianelle (1926) has reported more or less similar findings in the case of Friedländer's bacillus. A serum containing antibodies for one of the type-specific polysaccharides protects mice against the corresponding serological type. A serum containing only antibodies corresponding to the common nucleo-protein antigen affords no protection. A similar dependence of immunity on type-specific antibodies has been recorded for *Str. pyogenes* (Stamp 1936, Stamp and Hendry 1937) and *Sh. flexneri* (Weil and McFarlane 1944).

It was, however, in the case of the motile bacilli, possessing flagellar and somatic antigens, that the problem of the different immunizing value of different bacterial antigens was first stated in its clearest and most explicit form by Felix and his colleagues (see Felix 1924). The results of subsequent experimental studies have afforded strong support to his contention that the flagellar antigens, and the corresponding antibodies, play little if any part in the mechanism of specific antibacterial immunity, while the heat-stable somatic antigens and the antibodies that react with them are all-important.

Arkwright (1927) immunized guinea-pigs by the injection of vaccines prepared from different strains of *Salm. typhi* and *Salm. paratyphi A*, and subsequently tested their resistance by the injection of living virulent bacilli.

In the case of *Salm. typhi*, a vaccine prepared with a smooth, motile, virulent strain (containing the flagellar antigen and the surface antigen IX) produced a significant increase in resistance. A vaccine prepared from a rough, motile variant (containing the flagellar antigen but not the surface antigen IX) did not. In the case of *Salm. paratyphi A* four vaccines were used: (1) a smooth, motile strain, with the flagellar antigen and the surface antigens I, II, (2) a non-motile, smooth variant, with no flagellar antigen but retaining the surface antigens I, II, (3) a rough, motile variant, with the flagellar antigen but without the surface antigens I, II, and (4) a rough, non-motile variant containing neither the flagellar antigen nor the surface antigens I, II. Vaccines (1) and (2), containing the antigens I, II, produced a marked increase in resistance. Vaccines (3) and (4), from which this antigen was absent, did not.

Ibrahim and Schütze (1928) obtained analogous results in the immunization of mice against *Salm. typhi-murium*. They found that the R variants, in which the specific polysaccharide antigen was absent, were ineffective as immunizing agents. The S variants, containing the specific polysaccharide antigen, produced a significant increase in resistance.

Experiments, in which untreated mice and mice vaccinated with different bacterial suspensions were submitted to the risk of natural infection during a long-continued experimental epidemic of mouse typhoid, have yielded entirely concordant results (Greenwood, Topley and Wilson 1931). The total numbers in each of the vaccinated groups were large —over 300 mice—so that the difference noted may be regarded as certainly significant. The results are summarized in Table 73.

The column giving the antigenic structure shows the components on the surface of the bacterial cells and those carried by the flagella. All vaccines except E were saline suspensions, killed by heat and formalin. Vaccine E—a killed broth culture—was included because of the possibility that some bacterial product of immunizing value might be liberated into the culture fluid. The measure of resistance—the mean survival time in the epidemic cage limited to 60 days—was selected for reasons that will be referred to later. The significance of the standard error, which is attached to each survival time, has been considered in Chapter 43.

TABLE 73

Group.	Vaccine.	Antigens	Mean Survival Time in Epidemic Cage Limited to 60 Days.
C	*Salm. typhi-murium* . . . . . (Smooth—Type and Group)	Surface, IV, V, (XII). Flag. i. Flag. 1, 2, 3.	35·31 ± 0·884
E	*Salm. typhi-murium* . . . . . (Smooth—Type and Group—Broth culture)	Surface, IV, V, (XII). Flag. 1. Flag. 1, 2, 3.	34·97 ± 0·845
F	*Salm. paratyphi B* . . . . . (Smooth—Group)	Surface, IV, V, (XII). Flag. 1, 2.	35·06 ± 0·845
G	*Salm. paratyphi B* . . . . . (Smooth—Type)	Surface, IV, V, (XII). Flag. b.	33·71 ± 0·853
D	*Salm. typhi-murium* . . . . . (Rough—Type and Group)	Surface, R. Flag. i. Flag. 1, 2, 3.	29·41 ± 0·771
B	*Salm. typhi* . . . . . (Rough)	Surface, R. Flag. d.	29·28 ± 0·732
A	*Staph. albus*	—	29·86 ± 0·714
H	Unvaccinated Controls	—	26·26 ± 0·641

It will be seen that the control and vaccinated groups can be divided into three classes on the basis of their survival time. The unvaccinated mice lived, on the average, for 26·26 days, and were thus significantly less resistant than any other group. The groups D, B and A were slightly more resistant. This increased resistance was clearly not specific. The rough polysaccharide antigen was not concerned, for the *Staph. albus* vaccine did not contain it. The flagellar antigens of *Salm. typhi-murium* were not concerned, for neither the *Staph. albus* nor the rough *Salm. typhi* contained them. The groups C, E, F and G were definitely more resistant; their mean survival time varied from 33·71 to 35·31 days. They all differed from the other groups in that they contained the specific polysaccharide surface antigens of *Salm. typhi-murium* (IV and V). They differed among themselves with regard to their flagellar antigens. The results indicate quite clearly that the specific polysaccharide surface antigen is the most important immunizing agent. There is little doubt that the surface antigens of the salmonellæ are identical with the endotoxins that can be extracted from them (see, for example, Raistrick and Topley 1934, Boivin and Mesrobeanu 1936) and, as the experiment set out in Table 73 exemplifies, any cross-immunity induced by different salmonellæ is referable to their having a somatic antigen in common. These antigens stimulate the production of antibodies that have moderate anti-endotoxic powers, and are strongly antibacterial (Boivin and Mesrobeanu 1938*a*, *b*).

In the particular case of the typhoid bacillus it is necessary to discuss the significance of the Vi antigen and Vi antibody, described by Felix and Pitt (1934*a*, *b*) (see Chapter 69). The relation of the Vi and O antigens of *Salm. typhi* to antibacterial immunity is complex. Topley and his colleagues (1937) prepared an antigenic fraction containing a mixture of Vi and O antigens, and one containing the O antigen alone. On injection into mice, both conferred immunity to virulent Vi-containing typhoid bacilli. Later comparisons of relatively pure preparations of Vi and O antigen confirmed their immunological differences. Pure O and pure Vi sera specifically neutralized the *toxic* effect of the corresponding antigens, and exhibited a high degree of cross-protection against *infection* with *Salm. typhi* containing Vi and O antigens (Boivin and Mesrobeanu 1938*c*, 1939, Henderson and Morgan 1938, Boivin 1939). Henderson (1939), however, demonstrated a feebler protective action of O sera in mice when large infecting doses of bacilli were employed. He also showed that against infection with pure Vi and pure O strains of *Salm. typhi* only specific Vi and O sera respectively were protective (see also Grasset and Lewin 1937).

Robertson and Felix (1930) found that an antiserum to *Cl. septicum*, containing antibodies against the heat-stable somatic antigen, but none against the heat-labile flagellar antigens, had a high protective value in mice. Henderson (1932) recorded analogous results with *Cl. chauvœi*. These results accord in general with those found in the salmonellæ. But more recently Henderson (1937) observed that antisera to unheated formolized *Cl. septicum* contained a protective antibody specific for a heat-labile antigen in the bacilli. The antigen had none of the qualities of the heat-labile Vi antigens, and appeared to be flagellar in nature, the protective effect being roughly correlated with the flagellar agglutination titre. Henderson suggests that flagellar antibody might exert an immobilizing effect on a motile, pathogenic bacterium and thus prevent its dissemination through the tissues. If this is the case, it should be possible to demonstrate protection with flagellar antibodies in other types of infection.

The Efficacy of Antibacterial Immunity.

As we emphasized in the earliest pages of this book, immunity may be of very varying grade. The first effect of the mechanisms that we have discussed in this chapter is to free the circulating blood from bacteria, and so save the host from a fatal bacteræmia. The effect on the local foci of infection is less pronounced, and much less rapid. Bacteria may remain latent in such foci over considerable periods.

Thus (Topley 1929) of 64 vaccinated mice that had survived in apparent health for 28 days after an intraperitoneal injection of 1,000 virulent *Salm. typhi-murium*, 31 were found to be harbouring that organism in the spleen. We need not doubt that a complete sterilization of the tissues often occurs; but we must not identify the absence of overt illness with a complete absence of infection, or illness followed by recovery with infection followed by a return to the uninfected state.

There is another factor which may limit the efficacy of immunity of this type. There are regions of the body in which bacterial infections are particularly dangerous, and when foci are established at these sites an immunity that is effective against lesions elsewhere seems to be of little avail. Thus Bull (1915*b*) notes that immunized animals, after rapidly freeing their blood stream of pneumococci and remaining in apparent health for several days, may later succumb to a pneumococcal meningitis. The particular susceptibility of certain regions of the body, even in the immune animal, may be an inherent feature of the animal. It may also be a reflection of variations in the distribution and efficacy of antibody in the various tissues. We shall examine this latter possibility in the next section.

In general, antibacterial immunity is, as we should expect, found to be more variable and often less effective than antitoxic immunity.

The Conditions under which Antibodies exert their Protective Action.

The union of antibody with the surface antigens of an invading bacterium clearly renders the parasite more susceptible to the defence mechanisms of the infected host; for example, to the lethal and bacteriolytic action of complement and to phagocytosis. The importance for protection of the host of phenomena like precipitation and agglutination is less well established. The formation of visible precipitates, or of an agglutinated mass of bacteria, in the tissues or tissue fluids of an immune animal cannot take place unless there is an adequate concentration of antigen, either in the form of soluble products of bacteria, or of bacteria themselves.

In discussing the functional significance of precipitins Cannon (1940) suggests that specific aggregates in the body range in size from molecular aggregates up to large pre-

cipitates. The *in vivo* formation of large precipitates is, however, mostly a matter of conjecture, and while it is not to be doubted that antigen-antibody complexes of a molecular order of size are formed *in vivo*, they are clearly not precipitates. The reaction of the clearing mechanisms of the body to soluble antigen modified by union with antibody probably parallels the reactions to bacteria modified by antibody. As Cannon points out, soluble antigen disappears more rapidly from the blood of an immune animal than from that of a normal animal; but there is little evidence that the aggregates have to reach the size implied in the description "precipitate" before the clearing mechanism can take effect.

It is of interest to note that precipitation apparently plays an important part in immunity to certain parasitic nematodes. Immune sera precipitate with antigens contained in the excretory materials exuding from the mouth and anus of the worms. The resulting interference with the metabolism of the worms is lethal (see Taliaferro 1940, Oliver-González 1940).

Agglutination in the blood stream of the infected animal may be a prominent feature in the experimental tests of clearing mechanisms we have described above. It is, however, observed only with relatively enormous doses of bacteria (see, for example, Reiss 1939). It is probably less prominent in natural infections of the blood stream, where high concentrations of bacteria are unusual. In a local lesion, however, where the concentration of bacteria in the body fluids may be high, it is possible that antibody may help to localize the infection, not only by agglutinating existing bacteria, but by sensitizing growing bacteria so that their daughter cells, when formed, remain in a clump instead of dispersing.

The importance of agglutination as a protective mechanism in experimental pneumococcal infection has been stressed by Oelrichs (1934, 1935, 1936). Rich and McKee (1934) showed that antipneumococcal serum helped to localize experimental skin infections in rabbits whose leucocytic response had been inhibited by benzene poisoning. Wood (1941) found that in rats, the advancing edge of the pneumonic lesion consisted of a leucocyte-free zone of œdema, in which the alveoli contained only fluid and pneumococci. Nevertheless, when antipneumococcal serum was given intravenously, the spread of the infection was largely inhibited, and the pneumococci at the periphery of the lesion were at the same time agglutinated. A phagocytic response appeared later round the agglutinated masses, but prior to this, there was a definite association between localization of the disease, and the appearance in the infected tissue of agglutinating antibody. It is difficult to determine whether in these cases the agglutination is to be regarded merely as a consequence of an antigen-antibody reaction whose chief protective function is sensitization to phagocytosis (when phagocytes are present) and to the bactericidal action of the complement, etc., in the tissue fluids, or whether agglutination by itself is antibacterial. Aside from the purely mechanical effect of aggregation into large masses that are not readily dispersed through the tissues, there is little other protective function we could assign to agglutinins *per se*. Oldfelt (1942) reviews the evidence that bacteria are damaged by the action of agglutinins on living bacteria *in vitro*. Agglutination appears to have little effect either on the viability or on the respiratory activity of bacteria, except when the agglutinated masses are large. In these circumstances, Surányi and Pálóczy (1930), von Jenny and Váczi (1940) and Oldfelt himself recorded a diminution in the rate of oxygen uptake. At most, then, we may postulate that agglutination *in vivo* may be directly antibacterial when the agglutinated masses are so large as to interfere with the metabolism of bacteria in the centre of the masses.

The Availability of Antibody in the Tissues of the Host.

The concentration of antibody in the blood is one of the simplest indications of a state of immunity, and it is possible to determine by experiment the relation

between a given blood concentration and a specifically immune state of the animal. This immunity, however, depends on antibacterial qualities not only of the blood, but also on that of the tissues, the intercellular fluids, lymph, and so forth. Moreover, in most natural processes of infection, the defences come into play in the order—tissues, lymphatic system, blood stream, and finally reticulo-endothelial system. Given, then, an animal whose blood contains an adequate concentration of antibody specific for the antigens associated with the virulence of a parasite, we must consider whether the concentration of antibody in other tissues is sufficient for an effective antibacterial response at any of the stages of invasion we have listed. Serum antibodies, whether they result from active or passive immunization, are sooner or later distributed throughout the tissues. They are present in tissue fluids and lymph, but only in very low concentrations in cerebrospinal fluid (see Sohier and Jaulmes, 1939).

Thus Pagano (1894), Falloise (1903) and Batelli (1904) found that the concentration of hæmolysin was lower in the thoracic lymph than in the blood serum. Hughes and Carlson (1908), working with normal dogs, horses and cats, found that the concentration of hæmolysin for rabbit corpuscles formed a descending series, in the order—serum, thoracic lymph, neck lymph, pericardial fluid, aqueous humour. Becht and Greer (1910) studied the distribution of normal and immune antibodies in dogs. They also studied the rate of transference of antibodies from the circulating blood to the tissue fluids after passive immunization by the intravenous route. Their findings with regard to the distribution of normal and immune antibodies were in accord with those of Hughes and Carlson. In the actively immunized animals they observed a marked rise in the antibody titre of the serum, thoracic lymph and neck lymph, the relative concentrations in the different fluids maintaining the same order as in the normal animals. After passive immunization, by transfusion of blood from an immunized to a normal dog, the characteristic distribution of antibodies was established within $4\frac{1}{2}$ hours. These findings were confirmed in all essentials by Hektoen and Carlson (1910).

The thoracic duct, however, receives contributions from all the lymphatic channels of the body, including those from the liver, whose lymph ordinarily contains a high proportion of protein, so that the antibody content of thoracic duct lymph may reflect only the permeability of the liver capillaries to antibody. Thus Freund and Whitney (1929) injected agglutinins intravenously into rabbits and found that antibodies accumulated rapidly in liver lymph, slowly in lymph from the leg. Similarly, Becht and Luckhardt (1916) found cervical lymph had a lower concentration than thoracic duct lymph of intravenously injected antibody. In rabbits actively immunized with diphtheria toxoid, Takahashi (1936) found 0·67 unit of antitoxin per ml. of blood, and 0·29 unit per ml. of popliteal lymph. Nevertheless, with the possible exception of locally formed antibody (see Chapter 50) the concentration of antibody in tissue fluids and lymph, like that of other serum proteins, tends to be comparatively low. Thus in rabbits actively immunized with the virus of equine encephalomyelitis, the ratio of antibody titres in blood and brain tissue was found to be 120 : 1 (Morgan *et al.* 1942). In most cases the tissue antibodies are undetectable by direct titration of extracts (see, for example, Forattini 1937, Sedallian, Jourdan and Clavel 1938). With the onset of an inflammatory reaction, however, the greatly increased permeability of the capillaries and the lymphatics permits the exudation of antibody-containing plasma into the tissue spaces, and its drainage into the lymphatic channels. The concentration of antibody attained in the exudate varies with the nature and age of the inflammatory lesion (see, for example, Fox 1936) but in some cases it may equal that in the blood (see Finland 1932, Miles and Miles 1943).

The beneficial effects of this simple response may be reduced in a number of ways. The invading parasite may proliferate within the tissue cells (see Chapters 44 and 55) or it may be ingested by phagocytes. In both cases it will be protected from antibody

and other antibacterial substances in the blood. Thus Rous and Jones (1916) found that intraleucocytic typhoid bacilli were protected against antibody and against potassium cyanide; and similarly, Fothergill, Chandler and Dingle (1937) demonstrated that virulent influenza bacilli in the phagocytes of patients suffering from *H. influenzæ* meningitis were insusceptible to the action of specific antibacterial serum.

It is possible, too, that the capillaries may not permit the passage of the antibody molecule. The question arises particularly in the use of antipneumococcal horse sera, in which the antibody has a molecular weight of the order of 900,000, as compared with 150,000 for a normal serum globulin. It has been shown that rabbit antipneumococcal sera are more efficacious than horse antisera in experimental, and to some extent, in natural pneumococcal infections, and the effect has been ascribed in part to the greater penetrative power of the small rabbit antibody molecule (Horsfall, Goodner, McLeod and Harris 1937, Horsfall 1938). Haviland and McManus (1941), on the other hand, could find no difference in the diffusibility of rabbit and horse antibody into the inflamed pleural cavity of rabbits, but their inflammatory agent was a severe irritant and presumably induced maximum permeability in the blood capillaries.

The availability of tissue antibody is of paramount importance in the serum treatment of established infection. If exudation has already occurred in the inflamed region, then antibody introduced into the circulation will pass through the capillary walls with difficulty, owing to the hydrostatic pressure of the exudate already present in the tissues; in any event the antibody will be diluted in the existing exudate (Miles and Miles 1943); and the formation of extensive interstitial clots and intravascular thrombi (see Menkin above), or of dense and relatively avascular reacting tissue, may also prevent access of antibody to the infective lesion (see, for example, Kempf and Nungester 1939). Phenomena of this nature may also account in part for the therapeutic failure of antitoxin administered late in the course of a disease. In Chapter 46 we suggested that the failure might be due to a pharmacological inaccessibility of the toxin to antitoxin; but a mechanical inaccessibility is equally possible.

The availability of antibody in the tissues was studied along rather different lines by Friedemann and his colleagues. Friedemann and Zuger (1939*a*) observed that intradermal diphtheria toxin was fully neutralized in guinea-pigs already immunized with antitoxin, and that there was a linear relation between dose of toxin and dose of antitoxin. After the injection of toxin, neutralization could be achieved by the intravenous injection of antitoxin, but a comparatively much larger dose of antitoxin was required. The dose, however, was the same whether the antitoxin was given a few minutes after the injection of toxin, or up to four hours before; from which Friedemann and Zuger concluded that equilibrium between tissue and circulating antibody was reached a few moments after injection. Proceeding on this assumption, they attempted to measure the distribution of antibody between blood and tissue by comparing the concentration of antitoxin which neutralizes toxin on direct injection of the two into the tissue, with the blood concentration required to protect the tissue against a direct injection of toxin alone. In guinea-pigs the ratio of the two concentrations of antitoxin was about 20 for diphtheria and staphylococcal toxins given intradermally; in guinea-pigs and rabbits it varied between 50 and 1 for different batches of tetanus toxin given intracerebrally (Friedemann, Zuger and Hollander 1939, Friedemann and Zuger 1939*b*; see also Friedemann *et al.* 1944). It is recognized in this work that the ratios depend on the susceptibility of the animal tissue to the toxins, and variables of that nature, but the possible influence of changes in capillary permeability induced by the different toxins is not considered. Thus, the data supporting the hypothesis of a rapidly established equilibrium of antibody in blood and tissues are more readily explained on the assumption that the diphtheria toxin rendered the skin capillaries permeable for at least four hours, and, up

to that time, exudation of circulating antitoxins into the lesion was sufficient to suppress the typical toxic inflammation. Other workers find no evidence of a rapidly established distribution. Andersen (1937), for example, found that the antibody content of the skin of rabbits passively immunized against vaccinia by the intravenous route was relatively low after one day, and was equal to the blood content after 7 days.

These ratios, though they are not necessarily measures of the distribution of antibody between blood and tissues in the uninfected animal, are nevertheless indications of the magnitude of the antibody levels required in the blood of passively immunized animals for a protective effect in the tissues, irrespective of whether that protection is achieved by antitoxin already in the tissues, or by antitoxin exuding from the blood when the capillaries are damaged by the toxin. When we consider the greater complexity of factors concerned in action of tissue cells and fluids on bacteria, it will be clear that the blood levels necessary for the suppression of a tissue infection may be much higher (see also Fox 1943, Schlesinger, Olitsky and Morgan 1944).

The Availability of Antibody in the Lymphatic System.—Very little is known of the antibacterial effect of antibody in lymph We should expect that the lymph from an inflamed and infected region containing antibody would itself contain antibody and bacteria. Drinker and his colleagues (Drinker *et al.* 1935, Field *et al.* 1937) injected rabbits intravenously with virulent Type III pneumococci. Bacteria appeared, sometimes in large numbers, in the thoracic duct and in the cervical and leg lymphatics. The intravenous injection of moderate doses of antiserum was followed by a clearance of pneumococci from the blood, but not from the lymph; there was in some cases a small reduction of the bacterial content of the lymph when large doses of antibody were given. That the lymphatic system, which we have seen to be an integral part of the clearing mechanism of the body, should be demonstrably inaccessible to the sterilizing action of intravenously injected antibody, is a serious defect from the point of view of the serum therapy of infective disease, for bacteria in the lymphatic system will re-infect the blood stream as rapidly as it is sterilized, and vitiate the benefit conferred by the serum. The defect observed in Drinker's experiments may in part have been due to the relative impenetrability of the lymphatic system by the circulating antibody. Some antibody was found in the lymph of animals receiving large doses of antiserum, though not in very high titre. But even supposing that the antibody in the lymph was sufficient to sensitize any pneumococci present, it does not follow that the lymph would have been sterilized, since it contains few phagocytes capable of ingesting sensitized bacteria. For example, in heavily infected rabbits 88–95 per cent. of the lymph cells were lymphocytes, and no polymorphonuclear cells were seen. The defect, in fact, appears to be inherent in the animal, and not in the mode of serum therapy.

The Efficacy of Antigen-Antibody Union in vivo.—It must be remembered that the mere contact of antibody with bacteria does not necessarily ensure a maximum bactericidal effect. As we saw in Chapter 7, many *in vitro* antigen-antibody reactions take place with maximal effect only when the reactants are present in optimal proportions. In the therapy of natural infections by passive immunization, the only reactant we can vary, in quantity and quality, is antibody. It is not sufficient to assume that the largest practicable dose of antibody will necessarily be most successful.

Thus Goodner and Horsfall (1936) demonstrated that antipneumococcal horse antibody, which protected mice against virulent Type I pneumococci in a given dose, failed to protect in larger doses. In one experiment, pneumococci and serum were introduced into the peritoneal cavity of the mice. After four hours, in a mouse that had received

0·4 ml. of serum, there were about 215,000 extracellular pneumococci per ml. of exudate, and 24 per cent. of all the pneumococci present had been ingested by leucocytes; in a mouse receiving 0·05 ml. of the same serum, the corresponding figures were 690 extracellular pneumococci, with 97 per cent. of the total pneumococci ingested.

As in antitoxic immunity, the firmness of union between antigen and antibody is of considerable importance in bacterial immunity. Non-infective mixtures of bacteria and homologous antibody will become infective on simple dilution, indicating, as in analogous phenomena with "neutral" toxin-antitoxin mixtures, that some dissociation of the bacterium-antibody complex takes place. This dilution phenomenon was first demonstrated for bacteria by Enders and Shaffer (1937) and later by Morris (1940, 1941). The union appears to become firmer with the passage of time, for with prolonged contact of antibody and bacteria the dilute mixtures become less infective. Sabin (1935) found that mixtures of virus and antibody which were non-infective for one host given by one route might be infective when given by another route, or when given to another host, and postulated that the dissociation of antigen and antibody varied with the tissue and the animal. Morris (1944), taking fresh, complement-containing serum as a representative antibacterial tissue, tested its susceptibility to "infection" by *Salm. typhi*, with and without homologous antibody. Various specimens of fresh serum were alike in their susceptibility to bacilli alone, but varied greatly in susceptibility to mixtures of bacilli and antibody. She also observed two degrees of antibody action; a complete "neutralization," and, with less antibody, a modification of the bacilli that delayed their growth in the complement. The possibility of dissociation of antibody and infective bacterium, or of wide variations in susceptibility of tissues to "neutralized" and partly "neutralized" bacteria, has an obvious bearing on the problem of variations in the efficacy of antibody against bacteria in the different tissues and organs of the host, though at present we are largely ignorant of their significance in the elucidation of immune processes (see p. 1239).

Active Antibacterial Immunization as the Result of Infection.

We may close this chapter by considering what happens when a bacterium of moderate virulence obtains access to the tissues of a host that makes a successful immunizing response, and so recovers. We will take as an example a disease, such as typhoid fever, in which the bacterial parasite gains access to the blood stream and so is spread throughout the tissues during the early stages of the attack.

Fig. 247 shows diagrammatically the probable progress of an infection of this type. At A is represented the initial phase, during which the bacteria gain access through a mucous surface and pass to a regional lymphatic gland. At B the bacteria are proliferating in the gland, and there is an intermittent escape of some of them into the blood stream. At C these bacteria are shown as collecting in the liver and spleen, these organs being taken as examples of tissues rich in reticulo-endothelial cells, and hence concerned in the normal clearing mechanisms of the blood. At D the bacteria are proliferating in those situations in which they have collected during the initial phases of infection, which correspond to the incubation period of a clinical attack of disease. At E there is a re-invasion of the blood stream from these foci of bacterial proliferation, a well-marked bacteræmia, and a transport of bacteria to other tissues, not previously infected. This corresponds to the phase of clinical illness, and, in a fatal case, persists till death. Up to this stage no antibodies have appeared in the circulating blood; but at this point they usually make their appearance in cases that recover. At F is represented the phase of clinical recovery. The improved clearing mechanism, consequent on an efficient antibody-producing response, has terminated the bacteræmic stage; and we are left with a few scattered

foci of infection, in the spleen, liver and lymph nodes, and perhaps in other tissues. As we have seen, there is reason to believe that the persistence of this state of affairs over prolonged periods is consistent with the maintenance of apparent health. At G is represented the final stage of complete restitution, with the disappearance of all infecting bacteria, and the persistence in the tissues or body fluids of protective antibodies. It is probable that a proportion of infections may be terminated at

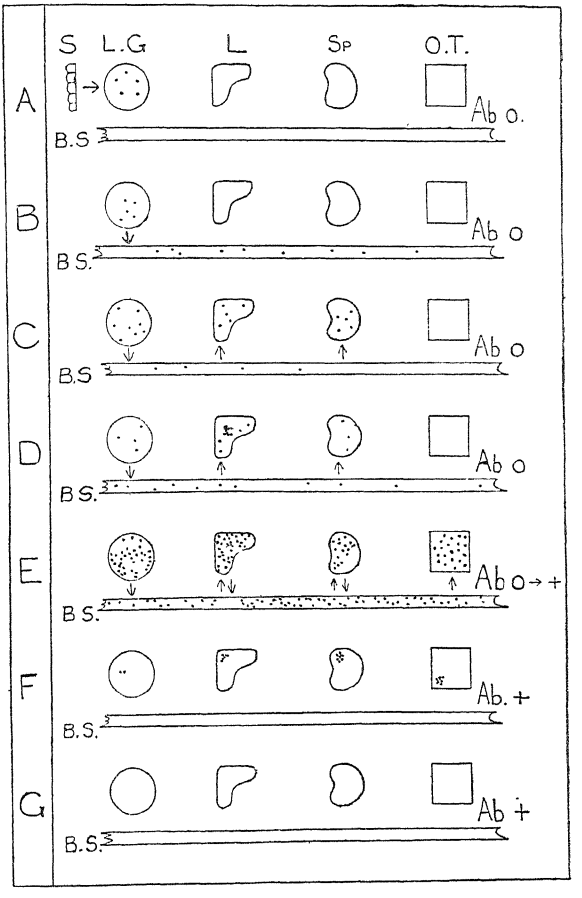

FIG. 247.

S = Mucous Surface. L.G. = Regional Lymphatic Glands. L = Liver. Sp. = Spleen. O.T. = Other Tissues. B.S. = Blood Stream. Ab.0. = Circulating Antibodies Absent. Ab. + = Circulating Antibodies present.

one of the initial stages, A, B, C or D, without ever passing to E, the stage of clinical illness; and there are reasons for believing that such abortive infections, especially if repeated, may lead to the acquirement of an effective degree of immunity to reinfection. With suitable modifications our diagram could be adapted to other bacterial infections, differing in regard to the primary focus of infection and the direction and extent of the secondary spread.

SUMMARY

(1) The mechanism brought into play in the removal of bacteria from the tissues is, in its main outlines, identical with that employed in the removal and storage of inert particles of the same order of size.

(2) When large numbers of bacteria are introduced directly into the blood stream they are in part taken up by the sessile histiocytes in such reticulo-endothelial depôts as the liver and the spleen, in part phagocytosed by polymorphonuclear cells and by macrophages in the lungs, in part flocculated into aggregates which are filtered off in the lung capillaries and later phagocytosed

(3) With avirulent bacteria, that have little power of multiplication within the tissues, this mechanism results in a rapid and permanent clearing of the circulation. With virulent bacteria an initial partial clearing is followed by a stage of bacterial multiplication in the foci to which the bacteria have been removed, resulting in a secondary invasion of the blood stream. The fate of the host is determined by the balance between this bacterial multiplication and the efficiency of the clearing mechanism. With slightly or moderately virulent strains there is a secondary bacteræmia followed by a secondary clearing. With highly virulent strains the secondary bacteræmia increases and the animal dies of an acute septicæmia. Even when secondary clearing occurs, and the animal remains in apparent health, foci of infection may remain in the various histiocyte depôts, and living bacteria may persist in these situations over long periods of time.

(4) When bacteria gain access to the body by other routes they are dealt with in part by local mechanisms of the same general character as that described under (3). The extent to which invasion of the blood stream occurs depends upon the anatomy and functional activity of the tissues first invaded, and upon the virulence of the invading organism. The blood stream is invaded very rapidly after intraperitoneal inoculation, less rapidly after intramuscular inoculation, and still less rapidly after subcutaneous inoculation. In all cases the passage from the primary site of infection to the blood stream is mainly by way of the lymphatics, and the histiocyte depôts in the regional lymphatic glands play a prominent part in the removal of the invading bacteria. When relatively avirulent bacteria gain access to the tissues at some site from which passage to the blood stream is slow, infection may never pass beyond the first line of defence in the regional lymphatic glands, but here, as in the case where a generalized infection has become established, localized foci of infection may persist over long periods of time.

(5) In addition to this process of removal by phagocytic cells, a direct bactericidal action of the serum plays a part in ridding the tissues of bacteria. The importance of this purely humoral immunity appears to differ widely in different bacterial infections ; but it is probably always subsidiary to the phagocytic mechanism, and is seldom, if ever, the main factor in defence.

(6) The efficiency of the clearing mechanism of a normal animal may be increased, *vis-à-vis* a particular bacterial parasite, by active immunization with a killed culture of that particular organism. The immunity so produced is specific in the serological sense. The actively immunized animal deals with a virulent strain of the bacterium against which it has been immunized in the same way as a normal animal deals with an avirulent or slightly virulent strain of the same bacterial species.

(7) Immunity of this type may be passively transferred by the inoculatio

into a normal animal of the serum obtained from an animal that has been actively immunized.

(8) The antibodies by which this passive immunity is conferred are those that unite with the surface antigens of the virulent bacteria; and in order to induce an effective active antibacterial immunity the immunizing agent employed must contain these surface antigens.

(9) The efficacy of humoral immunity in any part of the tissues is determined in the first place by the existing concentration of antibody on the cells or in the tissue fluid, and the availability of circulating antibody; and secondly by the presence, in optimal amounts, of the reactants, both fluid and cellular, necessary for the various antibacterial reactions of the tissues. It is probable that these factors vary widely in the different tissues of the animal body.

(10) The mechanisms described above come into play during the later stages of any bacterial infection that is associated with the development of an antibacterial immunity.

CHAPTER 48

THE AGGRESSIVE ACTION OF BACTERIA

In the preceding chapters we have considered the ways in which bacteria injure the tissues of an animal host, and the ways in which the host defends itself against attack. In the present chapter we are concerned with certain bacterial products which, though not in themselves grossly toxic to the host's tissues, exert an aggressive effect in bacterial infections by interfering with the host's defence mechanisms.

The available data are, as is so commonly the case, sadly confused by the fact that we have been forced to work with the crudest and most complex of reagents. The easiest way of disentangling, to some extent, the confused threads of this particular problem is to take as our starting-point a series of observations recorded by Bail and his colleagues (Bail 1900, 1902–3, 1904*a*, *b*, *c*, 1905, Bail and Pettersson 1902, 1903, Bail and Weil 1906, 1911, Weil 1905*a*, *b*). Working with the anthrax bacillus, with organisms of the *Pasteurella* group, with the cholera vibrio and with the typhoid bacillus, they found that exudates produced in experimental animals by the inoculation of these bacteria had characteristic properties, which Bail attributed to the presence of special bacterial products to which he gave the name *aggressins*; these aggressins were, he believed, produced in the tissues of the infected host, but seldom, if ever, *in vitro*.

The properties of aggressins, as described by Bail, may be summarized as follows:

(1) Sub-lethal doses of bacteria are rendered lethal by the addition of aggressins.

(2) A lethal dose of bacteria, which alone would produce a slowly fatal infection, causes a rapidly fatal infection associated with characteristic lesions when aggressins are added to the inoculum.

(3) The addition of cholera aggressins neutralizes the bactericidal action of an anticholera serum, as tested by intraperitoneal injection in the guinea-pig.

(4) By the injection of aggressins an immunity is produced which is far more effective than that produced by the inoculation of bacteria and is different in kind. This immunity can be passively transferred.

According to Bail, the aggressins are not themselves toxic. They produce their effects, which are in the main specific, solely by aiding the rapid multiplication of bacteria within the tissues. He states also that they are extremely thermolabile, being completely inactivated by 30 minutes' exposure to a temperature of 55° C. and markedly affected by any temperature above 44° C.

Bail's contention, that the results of his experiments required for their interpretation the assumption of the existence of a hitherto unrecognized bacterial product of peculiar importance in infection and immunity and deserving the new title of "aggressin," did not long remain unchallenged. Wassermann and Citron (1907) recorded their reasons for believing that the aggressins were simply products

of bacterial growth, or of bacterial autolysis, which could be prepared in the test tube by suitable methods. Citron (1906) recorded experiments which showed that the addition of bacterial extracts to living bacteria increased their virulence; that by the use of such extracts it was possible to immunize animals against experimental infection; and that the serum of such immunized animals conferred passive immunity on others. Bail and Weil (1906) maintained that the immunity produced by Citron with his bacterial extracts was far less effective than that produced by natural aggressins, and that it was different in kind; though it is not entirely clear on what differential criteria they relied in distinguishing anti-aggressin immunity from the varieties previously recognized.

Doerr (1906) criticized the aggressin theory on somewhat similar grounds, but emphasized particularly the fact that large doses of dead bacilli may cause death in experimental animals with the lesions described by Bail as characteristic of the aggressin effect. He also noted that if sub-lethal doses of killed cultures were added to sub-lethal doses of living bacteria the combined inoculum might cause a fatal infection of the aggressive type. This additive effect did not appear to be in any way specific, but some killed cultures were more effective than others. For instance, dead typhoid or dysentery bacilli were more aggressive than dead staphylococci. In addition, Doerr demonstrated that aggressive exudates did, in fact, contain ordinary bacterial antigens; since a typhoid exudate gave well-marked precipitation with an ordinary antityphoid serum.

Sauerbeck (1907) has also criticized Bail's hypothesis. He concludes, from the results of a large series of experiments, that aggressive exudates are not lacking in toxicity, since two or three times the amount that produces the characteristic aggressive effect will kill an animal within a few days in the absence of living bacteria; that the activity of a given aggressive exudate is in no way proportional to the virulence of the organism that produced it, but rather to its toxigenicity; that characteristic aggressive effects can be produced with toxic bacterial products that have been prepared in the test tube; and that aggressive action, whatever its cause, is entirely non-specific. His findings as regards the heat-stability of the aggressive bacterial products also differ from Bail's, since he states that they are reduced in potency, but not completely inactivated by heating at temperatures between 55° C. and 70° C.

The detailed studies of Dudgeon (1912) on the properties of exudates obtained from natural infections in man and from experimental infections in animals made it clear that one of the mechanisms involved in the total aggressin effect was a specific anti-opsonic action.

The method he adopted in the majority of his experiments was as follows. He obtained exudates from natural infections in man or from experimental infections in animals. The exudate, after the separation of as much material as possible by centrifugation, was mixed in a capillary tube with an equal volume of normal serum, or of serum from an immunized man or animal. After 1 hour's incubation at 37° C. leucocytes and bacterial suspension were added to each mixture, the tubes were re-incubated for 15 minutes and films were prepared from the contents, the degree of phagocytosis being determined in the usual way. In control tubes the exudate was replaced by saline. In each case the opsonic effect of the serum, and of the serum-exudate mixture, was determined against the bacterium causing the infection and against some related organism. The results shown in Table 74 illustrate an effect that was commonly observed. The exudate came from a subcutaneous staphylococcal abscess; the immune serum was from the infected patient; the normal serum was from an uninfected control. The sera and the serum-exudate mixtures were tested against the strain of staphylococcus grown from the abscess and against a strain of *Bact. coli*.

TABLE 74

Mixture.	Number of Bacteria ingested by 50 Leucocytes.	
	Staph. aureus.	*Bact. coli.*
Normal Serum + Saline	240	229
Immune Serum + Saline	294	203
Normal Serum + Exudate	139	200
Immune Serum + Exudate	139	237
Exudate + Saline	61	21

The exudate alone had a slight opsonic effect, but it specifically reduced the opsonic action of normal or of immune serum on *Staph. aureus*, leaving unaffected their opsonic action on *Bact. coli*.

The substances responsible for this specific anti-opsonic effect were found, in many cases at least, to be markedly thermostable. Table 75 shows the effect of adding a boiled exudate, obtained from an experimental infection with *Salm. enteritidis*, to the serum of the infected animal.

TABLE 75

Mixture.	Number of Bacteria ingested by 50 Leucocytes.	
	Salm. enteritidis.	*Bact. coli.*
Serum + Saline	248	130
Serum + Boiled Exudate	27	102

In further experiments Dudgeon submitted exudates to boiling, removed the coagulum by centrifugation, added excess of alcohol to the clear supernatant fluid, collected the precipitate by centrifugation, and redissolved it in saline. The preparation so obtained still showed specific anti-opsonic action.

These results bore an obvious analogy to an earlier series of observations (Dudgeon, Panton and Wilson 1909–1910, 1910–1911). Extracts were prepared from various bacteria by grinding or by alternate freezing and thawing, and these extracts were shown to have a specific anti-opsonic effect. The anti-opsonic substances were markedly thermostable, remaining active after boiling for 30 minutes. A considerable series of control tests showed that they had no direct action on the leucocytes.

In addition to these heat-stable specific anti-opsonic substances, Dudgeon found that many infective exudates contained directly toxic substances, as judged by injection into experimental animals. In this respect, however, they varied widely, according to the infecting bacterium. It may be noted that certain highly toxic exudates, such as those obtained in experimental infections with *Salm. enteritidis*, retained their toxicity after boiling.

Further light has been thrown on the probable nature of the anti-opsonic substances in aggressive exudates during the prolonged and detailed study of the factors involved in antipneumococcal immunity.

Rosenow (1907) found that extracts or autolysates of virulent pneumococci had the power of inhibiting the phagocytosis of relatively avirulent pneumococci, and he suggested the name *virulins* for the active substances concerned.

Cole (1917) observed that empyema fluids from pneumococcal infections contained soluble substances which specifically neutralized the protective antibodies in an antipneumococcal serum, and that similar substances might be present in the blood of rabbits suffering from experimental pneumococcal infection. He showed that, when an antipneumococcal serum was injected intravenously into a rabbit previously infected with the same type of pneumococcus, the protective antibodies disappeared very rapidly from the blood, and that a similar phenomenon could be demonstrated in patients severely ill with lobar pneumonia.

The more recent studies on the antigenic components of bacterial cells that we have outlined in Chapter 8, and the demonstration that sensitization to the phagocytic action of polymorphonuclear cells and macrophages depends upon the union of antibody with an antigenic component situated at the surface of the bacterial cell, offer the obvious suggestion that the substances responsible for the specific anti-opsonic effects of aggressive exudates are dissolved bacterial antigens. Landsteiner's demonstration of the inhibition of antigen-antibody reactions by simple haptens (see pp. 256–258), and the *in vitro* reactions of specific bacterial polysaccharides that fail to stimulate antibody production *in vivo*, indicate that bacterial haptens, as well as complete antigens, may be expected to exert this anti-opsonic effect.

There is good evidence that this is actually the case. Sia (1926) has studied the action of the type-specific polysaccharides of Type II and Type III pneumococci on the growth of these organisms in serum-leucocyte mixtures from the rabbit and from the cat. The pneumococci were of relatively low virulence and developed very poorly in either of the serum-leucocyte mixtures employed. The addition of minute amounts of Type II polysaccharide greatly increased the growth of Type II pneumococci, but had little effect on the growth of the Type III organisms. The addition of minute amounts of Type III polysaccharide greatly increased the growth of Type III pneumococci, but not of Type II.

Felton and Bailey (1926) have demonstrated the aggressive action of Type II polysaccharide by injecting it into mice together with relatively avirulent pneumococci of the same type, and inducing a fatal infection. Type I polysaccharide had analogous effects (Ward 1930). Ward and Enders (1933) demonstrated that the anti-bactericidal effect was due to the specific inhibition of phagocytosis. The anti-phagocytic action of the Type I polysaccharide as prepared in the laboratory was not so pronounced as that of Type II and Type III polysaccharides. Nor was it as pronounced as that of extracts of pneumonic lungs infected with Type I pneumococcus (Ward 1932). The discrepancy was later resolved by the discovery that the polysaccharide preparations, unlike native polysaccharide, were not acetylated (see Chapter 8). Acetyl polysaccharide proved to be fully anti-opsonic (Enders and Wu 1934). The aggressive effect of the pneumococcal polysaccharide in human infections is suggested by the work of Cole (1917) and Park and Cooper (1928), who record that a fatal outcome in cases of lobar pneumonia in man is frequently associated with the presence in the blood of specific soluble antigen in amounts greater than can be neutralized by the antibodies that the patient has produced.

Downie (1937) observed an aggressin-like effect of Type I pneumococcal polysaccharide. Mice immunized with a single dose of polysaccharide were resistant to a given dose of Type I pneumococci. If this dose was injected together with 0·05 mgm. of the same polysaccharide, the immunity was in most cases abolished. Nye and Harris (1937) calculated that the specific polysaccharide present in the lungs of certain patients dead of pneumococcal pneumonia would have required more than 60 litres of a good antiserum to neutralize it. Frisch and his colleagues (1942) have found up to 0·033 gm. of polysaccharide per 100 gm. of lung tissue in areas of grey hepatization due to Types I, II, VII and VIII pneumococcus, and in 10 cases of Type III pneumococcal pneumonia an average of 1·57 gm. per 100 gm., which corresponded to a total lung content

of 68 5 gm. of specific polysaccharide in a fatal case. This amount is serologically equivalent to 750 gm. of antibody nitrogen ; even if we suppose that not all of it must be neutralized before some of the antibody is available for a direct antibacterial action, it represents a reservoir of " aggressin " in the lesion of sufficient size to account for the failure of serum therapy in Type III pneumonia (see Chapter 74).

The capsular substance of the pneumococcus, besides having an aggressive action in its soluble form, *i.e.*, combining in the tissues with antibody that otherwise would opsonize the living bacteria, is associated to some extent in the intact capsule with the virulence of the organism. This association appears to be due in part to the resistance of capsulated organisms to ingestion, either by phagocytes (Ward and Enders 1933) or by the reticulo-endothelial cells of the whole animal (Enders, Shaffer and Wu 1936). A similar relation between capsular substance and resistance to phagocytosis has been demonstrated in hæmolytic streptococci (Seastone 1934, Lyons and Ward 1935) ; and Lyons (1937) records capsulation in young cultures of *Staph. aureus* associated with a greater resistance to phagocytosis than that displayed by non-capsulated forms.

The destruction of capsular substance, or inhibition of its formation, by the action of enzymes renders bacteria more susceptible to the defence mechanisms. Thus, the enzyme specific for the polysaccharide of the Type III pneumococcus is protective against infection by virulent Type III pneumococcal infection (Avery and Dubos 1931, Goodner, Dubos and Avery 1932). The hyaluronic acid content of the polysaccharide material in certain Group A and Group C streptococci (Seastone 1939, 1943, Kendall, Heidelberger and Dawson 1938) renders them susceptible to the action of hyaluronidase (see Chapter 44). Hirst (1941) protected mice infected with Group C, but not those with Group A, by treatment with leech-extract hyaluronidase. Blundell (1942) found only a feeble protective action in bull-testicle hyaluronidase in Group A infections ; and McLean (1942) none at all in both Group A and C infections, with doses of enzyme in excess of those required for decapsulation of the streptococci *in vitro*. Kass and Seastone (1944), however, report that bull-testicle hyaluronidase increases the bactericidal power of normal blood for Group A streptococci, and will protect mice against Group A infection.

It is possible that the Vi antigen of *Salm. typhi* (see Chapter 30), which is associated with the virulence of the organism, may act analogously to the capsular substances of the cocci. It is only one-fiftieth as toxic as the O endotoxin (Henderson and Morgan 1938) ; nevertheless, intravenous injection of extracts of Vi bacilli greatly reduces the protective effect of Vi antisera in mice infected with the living bacilli (Henderson 1939, see also León and Morales 1943).

In addition to these dissolved haptens or antigens it is clear that some infective exudates will contain other more or less toxic substances of bacterial origin that interfere with the defence mechanism of the host. Both Pettersson (1940) and Stevenson and Reed (1940) record a negative chemiotactic effect in *Staph. aureus* ; the substances responsible appeared to be distinct from the recognized components of staphylococcal toxin. Pettersson's substance, which he calls " negatactic," was antigenic, and antisera prepared against it had a protective effect in guinea-pigs and mice. Pettersson later (1943) found similar negatactic substances, distinct from capsular substances, in *B. anthracis* and pneumococci. The anthrax anti-negatactic sera appeared to act by permitting the infiltration into the infected tissue of active phagocytes. The pneumococcal negatactic substances displayed some degree of host-specificity ; the phagocytes of man and of the rabbit were susceptible to its action, but those of the mouse and guinea-pig were not.

In some cases, the frank toxins of a bacterium have an undoubted specific action on the defence cells of the host. Two pathogenic species, at least, *Staph. aureus* and *Str. pyogenes*, produce a specific leucocidin that attacks the polymorphonuclear cells ; and, for example, Dennis and Senekjian (1939) report an antigenic leucocidin in *Salm. typhi*. We know little as yet with regard to the action of bacterial toxins on the cells of the reticulo-endothelial system ; but it is quite

probable that we shall find that certain bacterial species are capable of producing toxins that have a selective action on the macrophages.

There are also the bacterial coagulases, fibrinolysins and spreading factors, which have been included among the bacterial toxins. It is clear that, in so far as they play an active part in the genesis of infection, they might, perhaps with better justification, have been described as aggressins. It is possible, too, that bacterial products may have a direct destructive action on protective antibodies. Beumer (1938) records that certain toxigenic strains of *Staph. aureus* were able to produce toxin in broth containing antitoxin, a capacity they owed to the elaboration of a proteolytic enzyme which destroyed the antitoxin.

In summary : it would seem that we are justified in recognizing the following factors as involved, to a varying degree, in the defence rupture that is produced by the injection of sterile infective exudates, of dead bacteria, or of bacterial extracts, in association with non-lethal doses of living bacilli.

(1) *Dissolved bacterial haptens or antigens, or similar components still attached to bacterial protoplasm.* These act specifically by uniting with the corresponding antibody, and so preventing the effective sensitization of the living bacterial cells. Many of them are thermostable, and many are predominantly polysaccharide in nature. These haptens and antigens are usually associated with the virulent forms of the bacteria in question, and in some cases are demonstrably derived from the bacterial capsule. It is probably only those haptens or antigens that are situated at the surface of the bacterial cell that are able to function in this way; since it is the surface components that are concerned in sensitization.

(2) *Bacterial toxins that selectively attack the cells concerned in tissue defence.* Their action is usually non-specific *qua* the infecting bacterium, since the injury to the phagocytic cells will reduce the efficacy of the defence mechanisms against other types of invading bacteria. The nature of the attack on the tissue cells ranges from inhibition of phagocytosis to complete destruction of the cell. These substances may be either "endotoxins" or "exotoxins." Endotoxins of this type, if they characterize the antigenic surface of the bacteria, will clearly have a twofold aggressive effect in infective exudates; a specific neutralization of opsonic antibodies and a direct attack on the tissue cells.

(3) *Other toxic bacterial products, bacterial enzymes, fibrinolysins, etc.*, that may act in any of the ways that we have considered in Chapter 44. In many such instances the effect may be merely additive—the tissues may have to deal simultaneously with a toxæmia and an invasive infection which have no direct connection with one another. In other cases the bacterial toxins, enzymes or hormone-like products may interfere with the defence mechanism of the host in various ways. In any case such action is probably non-specific in the immunological sense, though it is quite likely that a particular bacterial product may favour one type of infection more than another.

To which of these bacterial products, if any, should we attach the label *aggressin?* There seems little advantage in using it at all; it describes an effect, not a substance. There is, perhaps, something to be said for the term *aggressive action*, if we can so define it as to make it fill a gap in our terminology. It would seem to be most usefully employed as indicating an action on the cells or body fluids that is not directly injurious, or of which the directly injurious effects are minimal, but which so interferes with the defence mechanism of the host as to favour, specifically or non-specifically, the multiplication of bacteria within the tissues.

Used in this sense, it may be compared with the term *defence rupture*, employed to describe the action of certain chemical agents such as calcium, silica, and benzene (see pp. 1206–1209).

CHAPTER 49

THE NATURAL ANTIBODIES: THEIR NATURE, ORIGIN AND BEHAVIOUR

In the preceding chapters we have discussed the part played by antitoxins and antibacterial antibodies in the defence mechanisms of the host. We assumed, in that discussion, that these specific antibodies had been produced in response to artificial immunization or to natural infection. An adequate survey of any host species living under natural conditions will, however, show that many of the individuals composing it contain in their blood serum substances that react, *in vitro* and *in vivo*, in the same way as specifically induced agglutinins, or bactericidins, or antitoxins. The frequency of any particular antibody will be found to vary widely from one animal species to another, and often from group to group within the same species in accordance with age, or with some environmental circumstance.

The problems that concern us in this chapter are: (*a*) How do these natural antibodies arise? and (*b*) what part do they play in determining differences in natural immunity?

The Natural Antitoxins

The extensive evidence that we now possess with regard to the origin and significance of the natural antitoxins has, for the most part, been obtained in the study of two human infections, diphtheria and scarlet fever. It would, perhaps, be more natural to consider the relevant data in the chapters dealing with these two diseases; but it would be impossible to discuss our more general problem without frequent references to these particular instances, and it will therefore be more convenient to set out the evidence here.

That normal human beings may contain diphtheria antitoxin in their blood has long been known (Abel 1894, Wassermann 1895), but no extensive data on the distribution of antitoxin among the population at large were collected until after the description by Römer (1909) of the convenient intradermal technique for the measurement of small amounts of toxin and antitoxin. This was soon followed by the studies of Karasawa and Schick (1910), Schick (1911) and von Groer and Kassowitz (1915, 1917, 1919), which gave us a fairly detailed knowledge of the frequency of the presence of antitoxin among different age groups. The elaboration of the Schick test (Michiels and Schick 1913, Schick 1913), in which the presence of circulating antitoxin is detected by the insensitiveness of the skin to the intradermal injection of a small amount of toxin (the *negative* Schick reaction), has provided a still simpler method of detecting the presence of antitoxin above a certain level (1/100 to 1/30 unit of antitoxin per ml. of blood).

The proportion of persons who possess diphtheria antitoxin in the circulating blood varies in a striking and characteristic way as we pass from birth through

childhood and adolescence to maturity and old age. Table 76 sets out the extensive data recorded by Zingher (1923). It will be noted that the percentage of positive reactors is tabulated, *i.e.* the percentage that possess less than 0·01–0·03 units of antitoxin per ml. of blood.

At about 6 months of age just over half the infants tested react positively to the Schick test. The percentage of positive reactors then rises rapidly and between 8 months and 3 years fluctuates about an average value of approximately 88 per cent. After this period there is a continuous fall, at first rapid, then more gradual; between the 6th and 7th year the positive reactors number 50·4 per cent., by 12–13 they have fallen to 26·6 per cent., by 20–30 to 11·7 per cent., and at the allotted three-score years and ten to approximately 5 per cent.

The Origin of the Natural Antitoxins.

The most generally accepted view with regard to the succession of immunological events that underlie this observed fluctuation in skin-sensitivity to diphtheria toxin is as follows. At birth the majority of infants are endowed with circulating antitoxin which they have acquired passively from their mothers—mainly by passage of this antibody through the placental membrane, in part perhaps with the colostrum in the early days of suckling. This passive congenital immunity, like all other types depending on the passive acquirement of antibodies, will be relatively short-lived. A careful study of the disappearance of antitoxin from the blood of an infant whose mother was highly immune is recorded by Neill and his colleagues (1932). From infancy onwards the child will be exposed to the

risk of infection, increasing from year to year during the earlier part of school life. The result of this exposure will be that some children will contract the typical disease, while others will escape with mild and atypical infections, or with infections so slight that they fall wholly within the bacteriological as opposed to the clinical sphere. Each of these infections will stimulate the production of antitoxin, so that there will result a gradual process of natural immunization, the transitory passive immunity of early infancy being thus replaced, after a period of susceptibility, by a lasting active immunity.

This description, it should be noted, is not based on the results of Schick testing alone ; it is supported by a considerable body of evidence. Observations carried out by Römers' technique, and particularly the extensive series of observations made by von Groer and Kassowitz (1915), have shown clearly that the results of the skin test afford a reliable general indication of the frequency of circulating antitoxin in the different age groups. Thus 84 per cent. of infants at birth were found to have diphtheria antitoxin in their blood in a concentration of 1/200 A.U. or over, at ages 9–18 months the proportion had fallen to 32 per cent. and by 2½–3½ years to 28 per cent. It then rose steeply and by 17–18 years was back at the birth figure of 84 per cent. Later work has confirmed this picture, particularly the increasing proportion of Schick-negative persons with increasing age. The antitoxin blood level associated with the Schick-negative state, however, is not constant, some persons being positive with over 0 05 A.U. per ml. of blood, others negative with less than 0·005 A.U. per ml. (see Jensen 1933, Parish and Wright 1938).

There is, moreover, direct evidence that antitoxic immunity to diphtheria in infants results from transference of antitoxin from mother to child. Von Groer and Kassowitz tested the blood of 143 mothers and their new-born children. In 96 per cent. of cases antitoxin was present in both mother and child, or absent in both. Wright and Clark (1944), summarizing their own investigations and those of four other observers, found agreement in the Schick test of mothers and their infants in 84–85 per cent. of 713 tests.

Additional evidence of the transference of maternal antitoxins is provided by the observations of high antitoxin levels in the blood of infants whose mothers were immunized during pregnancy (see Magara 1936, Liebling, Youmans and Schmitz 1941), though in this case the possibility of a direct antigenic stimulus to the fœtus is less remote than in the cases cited above. In some instances discrepancies have been noted between the result of the skin test in infancy and the presence of antitoxin in the blood, a proportion of Schick-negative infants showing little if any circulating antitoxin (Kellogg 1926–7, Friedberger and Heim 1929, Okell 1932, see also Cooke and Sharma 1932). The Schick-negative state may in some cases be due to an insensitivity of the infants' skins that is independent of the presence of antitoxin (Dudley, May and O'Flynn 1934).

We may note here, although it concerns antibacterial antibodies, that the blood of infants of mothers actively immunized with *H. pertussis* vaccine contains a high level of protective antibodies against experimental *H. pertussis* infections (Cohen and Scadron 1943).

The mechanism of passive congenital immunity has been studied experimentally in animals. Ehrlich (1892), for instance, demonstrated the transference of anti-abrin and antiricin from female mice to their young by both the transplacental and mammary routes. It would seem that the relative importance of the two routes of transference depends upon the number of tissue layers that separate the maternal and fœtal circulation in different animal species. Table 77, taken from a paper by Mason, Dalling and Gordon (1930) sets out this relation in summary form.

Schneider and Szathmáry (1938, 1939, 1940) classified mammals according to the presence or absence of four out of a total of seven tissue layers between maternal and fœtal circulation. The results of their investigations with regard to the transmission of diphtheria antitoxin and agglutinins for *Salm. typhi* from maternal to fœtal blood are, however, essentially similar to those in the table, except that in dogs (*i.e.*, a carnivore) transmission *via* colostrum was marked, and placental transmission negligible.

TABLE 77

THE RELATIVE IMPORTANCE OF THE PLACENTAL AND MAMMARY ROUTES IN THE PASSIVE TRANSMISSION OF ANTIBODIES FROM MOTHER TO OFFSPRING. (After Mason, Dalling and Gordon.)

Species	Layers of Tissue between Maternal and Fœtal Circulation	Importance of Placental Transmission.	Importance of Transmission by Colostrum
Pig	5	−	+++
Ruminants	4	−	+++
Carnivores	2	±	+
Rodents, apes, man	1	+++	±

In man, antibody is present in the colostrum and milk, though usually in small amounts, unless the blood antibody levels are high. Immediately after delivery, for example, the diphtheria antitoxin content of the milk may be as high as one-third that in the blood, but it drops steeply during the first few days of lactation. Nevertheless, some transmission *via* the milk appears to take place (Sugg 1935, Magara 1936). Mice differ from other rodents in the table in that the mammary route appears in some cases to be more important than the placental. Thus, a higher degree of milk transmission of antibodies has been demonstrated experimentally in mice infected with herpes virus (Berry and Slavin 1943) and with *Trypanosoma duttoni* (Culbertson 1940).

Before considering the significance of the findings in the later age groups we may note that the distribution of scarlatinal antitoxin among the different age groups, as judged by the Dick test, appears to be essentially similar to that of diphtheria antitoxin. Table 78 gives the results obtained by Zingher (1924) in testing 7,700 persons.

TABLE 78

PERCENTAGE OF POSITIVE DICK REACTIONS IN DIFFERENT AGE GROUPS (ZINGHER).

Age Group.	Number of Persons Tested.	Per cent. Positive.
0–6 months	29	44·8
6–12 „	52	65·3
1–2 years	233	71 6
2–3 „	204	64·2
3–4 „	241	60·5
4–5 „	264	48·4
5–10 „	1,955	33·6
10–15 „	2,965	22·8
15–20 „	981	16·8
Over 20 „	776	14·4

It would seem that a negative Dick test during the first few months of life is as likely to be due to an insusceptibility of the infant skin to scarlatinal toxin as to the presence of antitoxin in the blood and tissue fluids. Cooke and others (1927, 1928) tested 200 mothers and their offspring. The results confirmed the rarity of positive Dick reactions in new-born infants; but the mothers of some of the negatively-reacting infants reacted positively, and some of the infants had no detectable antitoxin in their blood. When tested six weeks to three months later these infants were usually found to have become Dick-positive, while later still they became Dick-negative again. This reversion to the Dick-negative state was always associated with the appearance of antitoxin in the circulating blood.

A number of workers have recorded antistreptolysin in high titre in the blood of newborn infants, apparently derived from the mother. Though its significance is not clear it should be noted that these infant titres are sometimes found to be consistently higher than those in the maternal blood (see Plummer 1938, Gordon and Janney 1941).

Returning to the course of events from infancy onwards, are we justified in accepting the view that the acquirement of antitoxic immunity with increasing age is entirely due to natural active immunization resulting from the reception from without of specific stimuli in the shape of clinical or subclinical infections? This hypothesis has certainly not been placed beyond dispute. It has indeed been vigorously disputed, particularly by Hirszfeld (1926) and his colleagues.

Hirszfeld believes that all the normal antibodies should be regarded as "biochemical organs," with which the individual is endowed as the result of his evolutionary history. These "biochemical organs" ripen, or come to maturity, at different periods in his own individual development; just as the various organs and tissues of the body come to full maturity at different ages. As we speak of a "morphogenesis" through which each individual passes, so we should think of a "serogenesis" which forms an integral part of normal development. The time at which any particular antibody normally makes its appearance may be regarded as the period of "immunological crisis" for that particular antibody, and marks the establishment of a "biochemical reflex" on which the production of that antibody depends. Until the biochemical reflex has become established attempts at immunization with the particular antigen concerned will have little effect. Hirszfeld does not deny that specific, or non-specific, stimuli from without may play some part in accelerating the production of particular antibodies, or in increasing their concentration; but he would relegate such influences to a very secondary place. He would not regard the presence in the blood stream of antibodies acting on a particular bacterium as valid evidence of past or present infection with the bacterium in question. Above all, he would not accept the view that the antibody-forming apparatus is a *tabula rasa*, on which environmental stimuli can write at will. It is a complex mechanism with its possible activities fixed and ordered by the phylogeny of each animal species; and it will therefore respond to the appropriate stimuli and to no others.

It will be simpler to discuss the more general aspects of Hirszfeld's views when we have dealt with the origin of antibacterial sensitizers, and to confine our immediate attention to antitoxic immunity, noting in passing that the problem is in no sense a purely academic one but has important bearings on many problems of diagnosis and prevention.

Perhaps the most significant data, supporting Hirszfeld's contention, are to be found in observations (Hirszfeld, Hirszfeld and Brokman 1924, Hirszfeld and Hirszfeld 1927) which suggest a linkage between the inheritance of the power to produce antitoxin and the power to produce the iso-agglutinins which determine the human blood-groups (see p. 1087). From these records Hirszfeld draws the following conclusions. When both parents are Schick-negative the children will be Schick-negative, except during the first few years of life. When both parents are Schick-positive the children will be Schick-positive, and will remain so throughout life. When one parent is Schick-negative and the other Schick-positive the children who belong to the same blood-group as the Schick-negative parent tend to be Schick-negative, those who belong to the same blood-group as the Schick-positive parent tend to be Schick-positive (see also Tamaki *et al.* 1936). The validity of these observations has, however, been questioned by Rosling (1928), who examined 50 children over one year of age whose parents belonged to different blood-groups and reacted differently to the Schick test. He found that 23 children gave the same Schick reaction as the parent to whose blood-group they belonged, while 27 reacted differently.

A negative is notoriously difficult to prove; and we cannot assert that no child has ever developed diphtheria antitoxin except in response to the specific stimulus

provided by diphtheria toxin. We can, however, study the frequency of negative and positive Schick reactors in different samples of the population, and correlate our findings with the history of exposure to infection, so far as such a history is obtainable. If we find that free or frequent exposure to infection is consistently associated with a high percentage of negative reactors, while population groups that have been relatively free from any risk of infection show a notably low percentage of negative reactors, we shall be inclined to attach great importance to the part played by environmental stimuli, and to be a little sceptical as to the occurrence of spontaneous antitoxin production. The same holds, of course, in antiscarlatinal immunity and the Dick test.

Zingher (1923) noted that the proportion of Schick-positive children in different New York schools fluctuated very widely (14·62–70·13 per cent.), and that the schools with the highest percentage of positive reactors were those attended by the children of the more fortunate classes, who would have been less likely to have contracted the infection during early life, while a low percentage of positive reactors was found in schools attended by children of the poorer classes, and particularly in orphan asylums. The effect of institutionalism on the frequency of the Dick reaction is similar. Table 79 gives a series of observations recorded by Dyer and others (1926). Anderson (1943) reports a striking variation in the percentages of Schick-positive children according to their past experience of the disease : in the course of an extensive survey he found that 30·6 per cent. of children with a history of diphtheria, and 26·6 per cent. of children with a history of contact with diphtheria patients, were Schick-positive, while the corresponding rate in children with no history of the disease or contact with it was 90·9 per cent.

TABLE 79

PERCENTAGE OF DICK-POSITIVE CHILDREN IN CERTAIN SCHOOLS IN WASHINGTON. (After Dyer, Caton and Sockrider.)

School.	Age in Years.	No. Tested.	Per cent. Positive.
Suburban	3–15	75	77 3
Suburban	6–15	59	74·5
33 Rural Schools	4–21	1,147	72·5
33 Rural Schools	6–15	1,039	73·6
Episcopal Home	6–15	47	38 3
Orphan Asylum	3–14	80	32·5
Orphan Asylum	5–15	148	8·1

We might hope to obtain data of the same kind by comparing the frequency of Schick-positive reactions in countries where diphtheria is common with their frequency in countries where it is rare ; but the presence or absence of a particular disease among native races, and especially among their children, is less easy to determine than might be supposed, and such evidence as we have is conflicting.

Smits (1926) states that diphtheria is a very rare disease among the natives in the Dutch Indies, and it might therefore be expected that a high proportion of the native population would give a positive Schick reaction. This, he found, was not the case. Among 600 Javanese natives positive results were obtained in only 2 per cent. of the men and 8 per cent. of the women, while 41 per cent. of the children reacted positively. If the statement of the rarity of diphtheria could be accepted, this striking decrease in the proportions of Schick-positives with age would clearly support the view that antitoxin may be elaborated in the absence of any external specific stimulus. Kirschner (1929), however, records a detailed study of the prevalence of diphtheria in the Preanger district of Java during the period 1921–27, and notes the great increase in the number of recorded

cases which followed the provision of facilities for bacteriological diagnosis in 1923. He produces evidence that the disease is an important cause of mortality among native children and that a mild form is relatively common. We cannot, therefore, accept the findings with regard to the Schick test as supplying valid evidence in support of Hirszfeld's views.

Smits' observations do not stand alone. Heinbecker and Irvine-Jones (1928) performed Schick tests on 49 Eskimos; only 12 gave positive reactions, and of these 11 were under 12 years of age. Antitoxin was demonstrated in some of the negative reactors. Yet diphtheria is said to be unknown among the Eskimos.

Kleine and Kroó (1930) tested 101 East African natives by the Schick reaction; 95 of these were children between the ages of 6 and 15, the remaining 6 were adults. In no case was a positive reaction obtained. The toxin employed was subsequently retested and found to have lost none of its activity. Specimens of serum were obtained from 11 of the natives and tested for antitoxin; 10 of these contained antitoxin in considerable amount (0·05 A.U. to more than 1 A.U. per ml.). It is clear therefore that the East African native frequently forms diphtheria antitoxin early in life; yet, according to Kleine and Kroó, this population is not, so far as is known, exposed to infection with diphtheria. (See also Parr and Avery 1926–27, Parr, Goodale and Kirschner 1930.)

Grasset and his colleagues (1933) record a high frequency of natural diphtheria immunity among the Bantu of South Africa, as judged both by Schick tests and antitoxin titrations. They note, however, the occurrence of diphtheria among the populations concerned, and adopt without question the view that the antitoxin has been produced in response to infection. Murray (1943) provides more definite evidence. Among the Johannesburg Bantu clinical diphtheria was rare, but, as Grasset found in his series, the Schick-positive rate was low. In rural school children it was 8 0 per cent. and in urban children 13·7 per cent. The corresponding carrier rates of virulent diphtheria bacilli were 1·8 per cent. in the urban, and 3·2 per cent. in the rural; and though the Schick-positive rates and the carriers did not vary together, immunization was associated with the presence of carriers among the children. It is noteworthy that there was little clinical diphtheria among these Bantu children, as compared with white children in the same district, among whom a similar carrier rate was associated only with an epidemic of diphtheria; no bacilli were found in their throats in non-epidemic periods. Murray (1942) concludes that environmental conditions were in part responsible for the high level of antitoxic immunity of the Bantu, and that the absence of clinical diphtheria in spite of the relatively high carrier rate was due to an ability, perhaps racially determined, to produce antitoxin quickly in response to the specific antigenic stimulus (see Black 1934).

In only a few other instances do such surveys include a record of the carrier rate of diphtheria bacilli, or of hæmolytic streptococci, among the population concerned. Wells (1933), records a study of the Schick reactions of central and polar Eskimos, in which a proportion of tests were confirmed by antitoxin titrations, and throat swabs were obtained from all persons examined. He reports the frequent presence of bacilli morphologically resembling *C. diphtheriæ*, and states that four strains gave the typical fermentation reactions, and one strain showed some degree of virulence. These findings clearly tend to throw doubt on the significance of the observations recorded by Heinbecker and Irvine-Jones (1928), but it can hardly be said that the presence of toxigenic diphtheria bacilli was established with certainty.

A study by Asbelew and Margo (1932) of the Schick and Dick reactions of 103 of the 250 inhabitants of the Arctic island of Kolgujew is very difficult to reconcile with the *Durchseuchung* hypothesis—the view that antitoxin is produced only or mainly as the result of infection. With the exception of one girl of 8 years all persons examined were Schick-negative, and with the exception of one doubtful case all were Dick-negative. The antitoxin content of the blood was unfortunately not determined. Diphtheria and scarlet fever had never been reported on the island. Swabs were obtained from the throats of 168 persons, and from the noses of 93. No diphtheria bacilli were isolated, and hæmolytic streptococci were found in only four swabs.

There is great need of further studies in which full bacteriological and immunological tests are carried out on isolated or semi-isolated populations.

Although it is not complete, in this particular sense, the observations of Dungal (1932) on diphtheria in Reykjavik are particularly instructive. From 1926 onwards diphtheria has been very rare, not only in Reykjavik but in Iceland as a whole; but in the preceding years there was a moderate prevalence, reaching its peak in Reykjavik in 1921 with an attack rate of 6·9 per 1,000, and subsiding rapidly during the following 5 years. In December 1931 and during the early months of 1932 Dungal tested 814 school children in Reykjavik between the ages of 8 and 14 years. Of these, 81·9 per cent. gave a positive Schick reaction, a figure differing widely from that recorded in cities such as New York or London, where diphtheria is endemic. Still more significant, the curve describing the development of Schick immunity with age was of a very different kind. There was a trivial rise in the proportion of negative reactors from 13·97 per cent. in the 8-year age group to 17·24 per cent. in the 11-year age group; but there was a sudden rise to 26·36 per cent. among the 12-year-olds, and a further rise to 37·50 per cent. at 13 years. This clearly corresponds with the inclusion of children who had experienced the epidemic prevalence of 1921 and the

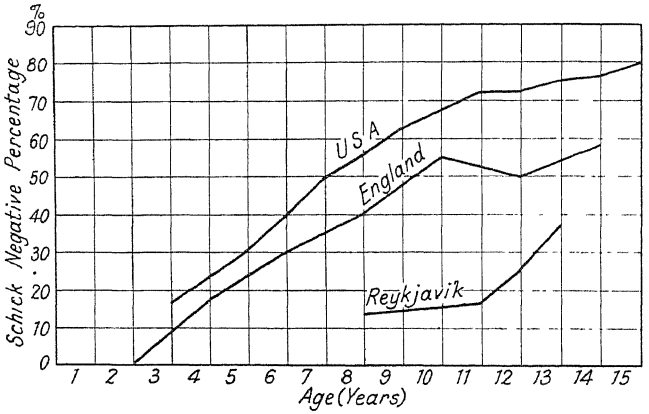

FIG. 248.

neighbouring years. Fig. 248, reproduced from Dungal's paper, illustrates these facts very plainly. Such an experience as this is clearly a weighty piece of evidence in favour of the dominant rôle played by latent infection in the stimulation of antitoxin production.

The semi-isolated population of Reykjavik provides yet another indication of the rôle of latent infection. Sigurjónsson (1939) noted that the duration of immunity following the immunization of children in the 7–13 year age group, estimated by the percentage of reversions from the Schick-negative to the Schick-positive rate during a four-year period, was much shorter than that in European children, though similar antigens were used in both cases. The European figures, however, were obtained from communities in which diphtheria was prevalent, whereas there was no clinical diphtheria in Reykjavik during the period of observation. The European immunity, it appears, was maintained by the continued stimulus of latent infections; in Reykjavik, where the risk of latent infection was minimal, the immunity declined more quickly.

One point of interest arises in the association of antitoxic immunity with carrier rates in a community, namely, the relation of avirulent strains of *C. diphtheriæ* to the immune state. By definition (see Chapter 61) the avirulent bacillus is non-toxigenic, and presumably is incapable of inducing an *antitoxic* immunity. The ratio of avirulent to virulent strains isolated varies from one community to another. Emmerson (1941) records a ratio as high as 13·5 : 1 in South Africa, and Forbes (1932) a ratio as low as 1 : 2 in London.

The lower ratios are usually found in white children living in relatively temperate conditions (Chason 1936, Gill 1940, Grossman 1940) and the higher with tropical conditions (Vardon 1923, Gomez and Navarro 1923); though Murray (1943) found ratios of 1 : 1 and 2 5 : 1 in South African Bantu, while Stebbins (1940) in New York State records 23 avirulent and no virulent strains in 1,800 children, of whom one-third were Schick-negative. We may regard these strains either as capable of producing minute but immunizing amounts of toxin and consequently of inducing a Schick-negative state in the carrier; or, as the experiments of Frobisher and Parsons (1943) on the immunization of rabbits with avirulent strains suggest, as inducing a useful anti-endotoxic immunity which may indirectly stimulate the increased production of antitoxin in subjects subsequently exposed to toxigenic bacilli. The high proportion of avirulents in some communities may, as Dudley (1929) has suggested, indicate a close adaptation between *C. diphtheriæ* and a population with a high level of immunity.

Taking the evidence from isolated, or semi-isolated, populations as a whole it can hardly be said to tell decisively for, or against, the *Durchseuchung* hypothesis. Its balance will depend, for each of us, on the particular records that inspire us with most confidence.

Another very instructive way in which we may obtain evidence with regard to the influence of environment on antitoxin production is to study *the rate of change* from the Schick-positive to the Schick-negative state under different conditions.

A good example is given by Zingher (1923), who records the percentage of Schick-positive children in different age groups among the inmates of a particular institution, dividing them into those who had been resident there for more or less than 3 months. The figures are set out in Table 80. The numbers examined in some of the groups were small so that the corresponding percentages must be accepted with caution; but there can be no doubt as to the significance of the marked difference between the recently admitted inmates and the older inhabitants. The institutional environment had clearly induced a swing from positive to negative reactiveness, with a velocity far higher than could be accounted for by changing age.

TABLE 80

PERCENTAGE OF CHILDREN GIVING POSITIVE SCHICK REACTIONS AMONG THOSE WHO HAD RESIDED IN A CERTAIN INSTITUTION, (*a*) FOR MORE THAN 3 MONTHS, AND (*b*) FOR LESS THAN 3 MONTHS, ACCORDING TO AGE GROUP. (After Zingher.)

Age Group.	Over 3 Months.	Under 3 Months.
4–5 years	23·8	66·6
5–6 ,,	27·3	33·3
6–7 ,,	17·0	43·0
7–8 ,,	13·9	43·7
8–9 ,,	4·6	33·3
9–10 ,,	3·8	9·0
10–11 ,,	1·6	33·3
11–12 ,,	5·0	25·0

Perhaps the most conclusive evidence of the effect of environment and infection is provided by such studies as those of Dudley (1923, 1926), who observed a small semi-isolated community of boys through a period of several years during which it was visited by three waves of diphtheria. By testing the Schick reactions at different periods he was able to demonstrate a wave of antitoxic immunization associated with each wave of disease.

During an extensive study of the relation of Dick reactivity to the prevalence of scarlet fever in Roumania, Schwentker, Janney and Gordon (1943) could find little evidence that

the acquisition of *Str. pyogenes* in the throat, or of infection with *Str. pyogenes* other than clinical scarlet fever, had any effect on the rate of change from the Dick-positive to the Dick-negative state. A similar rate of change, characterized by a slow increase in the earlier age groups, and a rapid increase with increasing age up to 20 years, was observed in a number of village communities, irrespective of the presence of scarlet fever (though in some cases an epidemic was followed by a general diminution in the percentage of negative reactors) and of other streptococcal infections. There was clearly an association between maturity and the acquisition of the Dick-negative state, but it was not clear how far latent infections could be altogether excluded as a contributory factor.

There is no doubt at all that the frequency of Schick and Dick reactors in any population or community in which diphtheria and scarlet fever are prevalent is determined very largely by the degree of exposure to infection ; and active immunization certainly plays a large part in natural antitoxin production under such conditions. It seems unlikely that antitoxin would be produced in the entire absence of such specific stimuli ; but we are not in a position to deny this possibility.

It is of some interest to note that numerous observers have recorded the presence of diphtheria antitoxin in the blood of normal horses. Sordelli (1920) found antitoxin in the blood of horses under 9 months old, presumably resulting from passive congenital immunization. No horse between 1 and 5 years of age possessed antitoxin, but the blood of all horses over 10 years of age contained detectable amounts. Glenny (1925) found 0·1 A.U. or more per ml. in 70 per cent. of horses over 7 years of age tested between the years 1907 and 1915, but in only 35 per cent. of those tested after 1917. He suggests that this difference may be due to the greatly lessened concentration of horses in towns during the later period, and a resulting diminution in the risk of infection. Lemetayer and de Diétrich (1936) record that no antitoxin was found in the blood of horses kept mainly at grass in a stud farm, whereas a fair proportion of stabled horses in surrounding farms, and from 50–70 per cent. of military horses, were positive. Ramon, Richou and others (1936) studied a number of immunized horses, and found that antitoxins were present only for those toxins of which the animals might reasonably be supposed to have had experience ; *i.e.*, the tests were positive for antitoxins of *C. ovis*, *C. diphtheriæ* and *Staph. aureus*, but not for anti-abrin or for the antitoxin to viper venom. A few well-documented instances are on record showing that horses are liable to natural infection with diphtheria bacilli. In most cases the organisms have been isolated from superficial wounds (Minett 1922, Kliewe and Westhues 1925, Parish and Okell 1926) ; only in a few instances have they been demonstrated in the throat (Cobbett 1899, Ramon 1925, Zuruk-zoglu and Mündel 1935*a*, *b*). We have, however, no adequate evidence with regard to the frequency of such infections, so that we cannot tell whether the presence of antitoxin in the blood, as recorded by Glenny, can reasonably be attributed to external stimuli of this kind.

Natural staphylococcal antitoxin is found in the blood of guinea-pigs. The rôle of exposure to environment in the stimulation of antitoxin was studied by Ramon and Richou (1936), who found that 77 per cent. of guinea-pigs kept in stables had a serum-content between 0·1 and 20 international units per ml. ; while the corresponding figure for guinea-pigs kept in open fields was 5 per cent. They later showed that guinea-pigs, kept in contact with guinea-pigs with a high natural antitoxin content, themselves developed a high content, in contrast to segregated control guinea-pigs, which developed no antitoxin (Ramon, Richou and Djourichitch 1936).

The Immunological Significance of the Natural Antitoxins.

Whatever the mechanism of their production, there is no doubt that the natural antitoxins confer on their possessors a significant degree of immunity. Direct experimental evidence is, of necessity, scanty ; but so far as it goes it is demonstrative.

Guthrie, Marshall and Moss (1921) collected 8 volunteers and determined their reaction to the Schick test; 4 reacted positively and 4 negatively (including 2 pseudo-reactions). The throat of each of these 8 volunteers was swabbed with a virulent culture of the diphtheria bacillus. The four positive reactors developed clinical diphtheria; the 4 negative reactors, possessing natural antitoxin at or above the Schick-immune level, developed no illness, though 3 of them became carriers.

The main body of evidence on which we rely in concluding that natural antitoxin confers natural immunity has, however, been collected during the course of extensive clinical and epidemiological studies on diphtheria and scarlet fever (see Chapters 61 and 66). There is no doubt that a person whose blood contains antitoxin at or above the Schick-immunity level is far less likely to contract diphtheria than a Schick-positive person. If he does so, the attack will often be mild and will seldom prove fatal. The nature of the evidence that associates natural antitoxin immunity with effective resistance to scarlatinal infection is of the same general kind as in the case of diphtheria.

The Natural Antibacterial Antibodies

It has long been known that there are naturally occurring agglutinins, bactericidins and other sensitizing antibodies, just as there are naturally occurring antitoxins; but the ground that has been surveyed in the two cases is rather different. We have seen that our knowledge of the distribution and mode of origin of the natural antitoxins is, in the main, derived from the study of diphtheria and scarlet fever in man. Our knowledge of the distribution and mode of origin of the antibacterial sensitizers is, in the main, derived from studies on their occurrence in different species of animals.

One of the earliest studies of this kind was recorded by Burgi (1907). He tested sera from the dog, guinea-pig, rabbit, goose, hen, sheep, goat, horse, ox and man against suspensions of various bacteria, including *V. cholerœ*, *Salm. typhi*, *Bact. coli*, *Past. aviseptica*, *Staph. aureus* and *Proteus vulgaris*, and noted well-marked agglutination in many instances, often to a relatively high titre. He found, however, that the various sera tended to be arranged in very much the same order of activity, against whichever species of organism they were tested; and, in further experiments, that this order was in general maintained when the sera were tested for their ability to flocculate suspensions of mastic.

Gibson (1930) carried out similar experiments with sera from the ox, rabbit, guinea-pig, horse, sheep, pig, rat, cat and man, tested against *Proteus X*19, *Ps. pyocyanea*, *Salm. typhi*, *Salm. paratyphi A*, *Salm. paratyphi B*, *Salm. enteritidis*, *Sh. flexneri*, *Sh. shigœ*, *Proteus morgani*, *Bact. friedländeri*, several strains of *Bact. coli*, and *V. cholerœ*. He found, as Bürgi had done, that the sera tested tended to fall in a definite order with regard to their power of agglutinating a wide variety of bacteria. Ox sera were the most active; pig and horse sera were somewhat less active; sheep serum was next in order; while human, cat, rabbit and guinea-pig sera, in that succession, showed progressively weaker effects. Rat serum was the weakest of all. Similarly the different bacterial species showed a definite order of sensitivity to agglutination. *Sh. flexneri*, *Bact. friedlanderi* and *Ps. pyocyanea* were the most sensitive, while certain strains of *Bact. coli* were least sensitive. By absorption experiments, Gibson was able to show that this agglutination was dependent on the presence of specific antibodies; but since any one organism, in addition to removing completely the specific agglutinin acting on itself, might reduce the titre of the serum for other organisms, and a similar general reduction in titre might be produced by adsorption with some non-specific agent such as charcoal, he concluded that another non-specific serum constituent was concerned in the full effect obtained with the untreated sera. In later experiments (Gibson 1932), in which the H and O

antigens and antibodies were differentiated, he obtained results suggesting that the specificity was due mainly to the H agglutinins, while the O agglutinins for any one bacterium might be greatly reduced by absorption with an antigenically unrelated organism.

Timmerman (1930) tested sera from the guinea-pig, rabbit, hare, goat, sheep, buffalo and man against *Salm. typhi* and was able to demonstrate the presence of both somatic (O) and flagellar (H) agglutinins in one or more specimens of serum from each species, except in the case of the guinea-pig, in which 2 of 20 animals showed O but no H agglutinins.

Lovell (1932) tested the sera of 202 normal swine, 23 cattle, 46 sheep and 20 horses for flagellar agglutinins against 7 different types of salmonella bacilli. Normal agglutinins against one or more of these types were present in 190 swine, 13 cattle, 36 sheep and 18 horses, usually to relatively low titre. Absorption experiments indicated that these agglutinins were in most cases specific. In further studies (Lovell 1934) he tested the sera of 263 normal swine, 163 cattle, 71 sheep, 40 horses and 40 rabbits for H and O agglutinins against *Salm. typhi-murium*, *Salm. newport*, *Salm. choleræ-suis* and *Salm. enteritidis*. The great majority of the pig, cattle, sheep and horse sera showed the presence of flagellar agglutinins for some, or all, of these species. A rather smaller, and more variable, proportion showed the presence of somatic agglutinins. As in the earlier study, absorption tests gave clear indication of specificity, though in some instances there were minor degrees of cross-absorption. The rabbit sera seldom showed the presence either of flagellar or somatic agglutinins. Mackie and Finkelstein (1930, 1931, 1932) (see also Finkelstein 1933) have tested the serum of a number of normal animals, such as the ox, sheep, horse, pig, rabbit, rat, cat, guinea-pig, pigeon and man, against a variety of bacteria, including *V. choleræ*, *Salm. typhi* and other members of the *Salmonella* group, dysentery bacilli, proteus bacilli, influenza bacilli, *Br. abortus*, *Br. melitensis*, meningococci and so on. They have also (Mackie *et al.* 1932) tested the bactericidal action of whole blood and of serum-leucocyte mixtures. They were able to demonstrate complement fixation and bactericidal action in a large number of cases, and to show that the bactericidal effect depended on the joint action of complement and a heat-stable factor that could be removed by absorption. This absorption was specific, in the sense that it was often possible to demonstrate the removal of bactericidal power against the absorbing organism while the absorbed serum was still bactericidal for other bacteria.

Gordon and Carter (1932) record results which lead them to a different conclusion. Testing rabbit and guinea-pig sera against cholera vibrios, typhoid and other salmonella bacilli, and dysentery bacilli, they were able to demonstrate a well-marked bactericidal action that depended on the interaction of complement and some heat-stable factor; but they failed to demonstrate any specific absorption of the latter. Their results suggested that the bactericidal activity against the less sensitive organisms could be removed by absorption with many different bacteria, leaving in each case an effective residuum of bactericidal action against those organisms, such as the cholera vibrio and the dysentery bacillus, that are particularly sensitive to serum lysis. Gordon and Johnstone (1940) later demonstrated a certain degree of specificity in normal rabbit, guinea-pig and human sera, in that, though absorption by heavy suspensions of one bacterium reduced the bactericidal power for a number of unrelated organisms, there was a much greater reduction of bactericidal power for the absorbing bacterium. They suggested as a possible alternative to the hypothesis of strain-specific antibodies, a specific alteration of a general bactericidal antibody during the process of exposure to the "absorbing" organism.

To summarize these findings: the serum of most normal animals contains substances that react with bacteria in the test-tube giving agglutination, complement fixation and bacteriolysis (bactericidal action). The sera of some animals, such as pigs and cattle, seem to react with a wider variety of bacteria than do the sera of other animals, such as the rabbit and guinea-pig. Different species of bacteria also vary in their sensitiveness to normal sera. Some species are agglutinated, or lysed, by normal serum from many different animals, others are sensitive

only to a few. The specificity of the flagellar agglutinins in normal sera seems to have been clearly established, and the evidence is definitely in favour of the specificity of some, at least, of the agglutinins acting on the antigens at the surface of the bacterial cells. These agglutinins, flagellar and somatic, are, it should be noted, usually present in low titre only (1 : 5–1 : 40 or thereabouts). The evidence with regard to the specificity of the bactericidal antibodies is more conflicting; but results indicating specificity have been recorded, and if somatic agglutinins are present we should expect them to exert a bactericidal action in the presence of complement.

In view of the divergence of evidence and opinion referred to above, it may be well to discuss this question of specificity a little more fully. The conclusion that the natural antibacterial sensitizers are specific does not, of course, imply any particular hypothesis as to their mode of origin; it assumes only that they unite with certain bacteria because of a chemical affinity conferred by certain specific combining groups.

We need not, therefore, assume that the natural antibodies are in all cases identical with those induced by active immunization. A "natural" antibody and an "immune" antibody, both acting on the same bacterium, must each possess chemical groupings with a specific affinity for groupings borne by the bacterium; but, if the natural antibody has arisen in some way other than in response to infection with the actual bacterium concerned, it is quite possible that the chemical correspondence between its active groupings and those on the bacterial surface will be less close than in the case of an antibody produced in response to infection or artificial immunization. There are certain experimental findings that are in accord with such a possibility. It is, for instance, a very general experience that some, at least, of the "natural" antibodies require, for their removal from a serum, an absorbing dose of bacteria very much larger than that required for the removal of the same amount of an "immune" antibody.

If we adopted this view we should expect that the antibacterial antibodies demonstrable in any random sample of a human or animal population would be of two kinds, those arising as the result of infection with the bacterium on which they act, and those arising in some other way. This brings us directly to the question of their origin under natural conditions.

Some Examples of Natural Agglutinins.

It is, of course, well established that certain kinds of "natural antibodies" are produced in the absence of any environmental stimulus, and in accordance with definite genetic laws.

The best example is perhaps provided by the isohæmagglutinins that divide mankind into different blood-groups.

Landsteiner (1901) distinguished the principal blood-groups into which the human race may be divided, and showed that this grouping depends, in the main, on the distribution of two different antigenic constituents, which may be present together, or separately, or may both be absent. There are two corresponding antibodies, and these are so distributed that neither antibody is present in the blood of an individual whose red cells contain the corresponding antigen. By determining the antigens present in any sample of blood it is therefore possible to assign it to its correct group. Two ways of numbering the four main blood groups were devised (Jansky 1908, Moss 1910), which in the past led to confusion. The terminology of the groups adapted from that of von Dungern and Hirzfeld (1910–11) is to be preferred. The antigens are referred to by a

capital letter, the antibodies by Greek letters, and the blood group to which an individual belongs is conveniently named according to the presence or absence of the A and B antigens. The constituent factors of the four groups can then be set out as follows:

Antigens	O	A	B	AB
Antibodies	$\alpha\beta$	β	α	—

The serum of a Group O blood will agglutinate the corpuscles of Groups A, B and AB, for it contains the antibodies α and β; but the corpuscles of this group will not be agglutinated by the serum of any group, since they contain neither of the antigens A and B. A person belonging to this group is a "universal donor"; his blood can be transferred with safety to any recipient, but he can only receive with safety the blood of a person belonging to the same group as himself. The interactions of the other groups will be obvious, and it will be noted that a member of Group A can receive blood from Groups O and A, a member of Group B from Groups O and B, while a member of Group AB can receive blood from any group, since his serum contains no antibodies, but can donate blood only to a member of his own group. It should be noted that there is an antigen characterizing Group O cells, but the occurrence in human sera of antibodies specific for O is extremely rare. The blood cells of man are also characterized by one, or both, of two antigens M and N (Landsteiner and Levine 1928) but, as with the O antigen, naturally occurring antibodies to M and N are exceedingly rare. Recently Landsteiner and Wiener (1940, 1941) discovered that the sera of rabbits immunized by the erythrocytes of the *rhesus* monkey would agglutinate those of certain human subjects, and added the Rh antigens to the list of antigens already characterizing the human erythrocyte. The presence or absence of these antigenic components, and of the various subgroups that have been described, is determined genetically according to Mendelian principles; the A, B and O antigens form one system, in which A and B are dominant to O (Hirzfeld 1926, Bernstein 1924); the M and N form a second (Landsteiner and Levine 1928) and the Rh antigens a third, in which the presence of Rh is dominant to its absence (Wiener 1942, Race and Taylor 1943, Race, Taylor *et al.* 1943, Race 1944).

This brief description does not include some minor antigens present in certain blood cells and must necessarily ignore the far-reaching developments in genetics, in the pathology of blood diseases and in immunochemistry, that have arisen from Landsteiner's original discovery. We are concerned here with the relation of certain antigens to the presence of antibodies in the blood. The presence of two antibodies, the α and β agglutinins, is either genetically determined, or is dependent on some other genetically determined factor such as absence of the corresponding antigens in the red cells of the blood.

The Rh antigen is of particular interest. Unlike the A and B, and like the O, M and N antigens, its presence in the cell is not invariably associated with the absence in the serum of corresponding antibodies. In certain circumstances, in fact, it is antigenic in man; and the conditions in which it is able to immunize man, and the consequences of that immunity, are highly instructive from the immunological point of view. Among British and white American people, about 85 per cent. of the population are Rh-positive, the remainder Rh-negative. If an Rh-negative woman mates with an Rh-positive man, the fœtal erythrocytes may be Rh-positive, and in a certain number of cases, depending perhaps on the condition of the placenta, the Rh antigens of the fœtus are transferred to the mother, and induce the formation of Rh-agglutinins. Towards the end of pregnancy, these agglutinins appear in the circulation of the fœtus, and, uniting with the fœtal erythrocytes, sensitize them to lysis, in a manner analogous with the sensitization, let us say, of Group A cells transfused into a Group B person with natural α agglutinins in his serum, The resulting destruction of the red cells may lead to the death of the fœtus and abortion, or the birth of an infant with the syndrome known as erythroblastosis fœtalis (Levine. Burnham, Katzin and Vogel 1941, Levine, Katzin and Burnham 1941, Boorman, Dodd and Mollison 1942). We have here a clear-cut example of the absorption of antigens through the uterus, and of the placental transmission of maternal antibodies. The Rh

antibody may also be transmitted by the colostrum. There is clearly a difference between the action of maternal Rh-agglutinins and the maternal α and β agglutinins, for it is only rarely that marked blood destruction occurs in infants of the A, B, or AB groups whose mother's blood contains corresponding natural agglutinins. We may postulate a selective transmission of Rh, but not α or β agglutinins, or that the infants are in some way insusceptible to α and β agglutinins. The second explanation seems more likely to be correct. It has been suggested that the cells of the infant are protected from α and β agglutinins of the mother by water-soluble Group A or B substances which are present in the tissues and body fluids of the infant, and which unite with any maternal agglutinins that reach the fœtus. It is known that in the majority of persons, the group A and B substances of the red cell are also present in the tissue fluids; they have been found, for example, in urine (Yosida 1928), gastric juice (Witebsky and Klendshoj 1940), saliva (Landsteiner and Harte 1941) and in the secretions of pseudomucinous ovarian cysts (Morgan and van Heyningen 1944). The Rh substance, on the other hand, is confined largely to the erythrocytes (Levine and Katzin 1941, Wiener and Forer 1941) and to the fœtal tissue cells (Boorman and Dodd 1943), but is not present in the tissue fluids, and, as a result, is not available for the neutralization of maternal Rh-agglutinins. (For a full discussion, see Levine 1943). The effect of A and B substances is analogous in one respect with that postulated in Chapter 48 for the aggressive action of bacteria; in the one case the soluble bacterial antigens neutralize antibacterial antibody, and so protect the bacterial cell from opsonization, and in the other, soluble erythrocyte antigens protect the red cell from specific sensitization to lysis

In addition to these isoagglutinins and isolysins—antibodies acting on the corpuscles of other individuals within the same species—the sera of all animal species that have been examined have been found to contain antibodies acting on the red cells of certain other animal species. The kind, number and activity of these antibodies vary from one species to another in the same way as the bacterial sensitizers described earlier in this chapter. The pioneer researches of Ehrlich and Morgenroth (1899, 1900*a*, *b*) established quite clearly, by means of absorption tests, the specificity of the antibodies concerned.

Forssman and Related Antibodies.

In this connection and because it has a direct bearing on the problem with which we are mainly concerned—the origin and nature of the natural antibacterial sensitizers—brief reference must be made to an antigen-antibody reaction of a curious and interesting kind which was first described by Forssman (1911), who observed that the injection into rabbits of organs obtained from the guinea-pig, or from certain other animals, led to the production of hæmolysin for sheep's red corpuscles. These observations have been confirmed and extended by many subsequent workers (see Taniguchi 1919–20, 1921, 1922, Browning 1931); and it is now known that the so-called *heterophile* or *Forssman* antigen, which is responsible for this reaction, is widely distributed among different animal species, and in a curiously random fashion. Thus the organs of the guinea-pig, horse, dog, cat, mouse, fowl and tortoise stimulate the production of heterophile antibody when injected into the rabbit, while the organs of man, rabbit, ox, sheep, rat, goose, pigeon, eel and frog do not. The organs and tissues that have been examined with regard to the presence or absence of heterophile antigen include kidney, liver, lung, adrenal, testicle, heart, skeletal muscles, lymph glands and serum, though not all of these have been tested in the case of each of the species enumerated above. It is noteworthy that the organs of the sheep, freed of all red corpuscles, do not stimulate the production of heterophile antibody; and in general it appears that those species that contain heterophile antigen in their red corpuscles do not contain it in their tissues, at least in the full and effective antigenic form.

It soon became clear, from absorption experiments of the usual type, that the hæmolysin produced by the rabbit in response to the injection of guinea-pig's kidney was not

identical with that produced in response to injection with sheep's corpuscles. The hæmolytic serum in the latter case contains a mixture of hæmolysins, only one of which corresponds to the heterophile antigen.

It should be noted that only animals of the rabbit type—those not containing heterophile antigen in their tissues—are capable of producing heterophile antibody in response to the injection of guinea-pig's kidney or other suitable tissue. It is also of particular interest from our present point of view that certain normal antibodies are of the heterophile type—for instance, the natural hæmolysin for sheep's red cells that is found in the serum of rabbit and man (Friedemann 1917). In the case of human serum, this reaction may depend on the α isoagglutinin, for, as Schiff and Adelsberger (1924*a*, *b*) showed, there is a close antigenic relation between the heterophile antigen and the Group A substance.

The constitution of the heterophile antigen appears to vary with the organism in which it is found. According to earlier workers (Iwai 1917, Georgi 1919, Taniguchi 1921) the specific component (hapten) is associated with lipoid constituents of the tissues, especially the alcohol-soluble " lecithin " fraction. The heterophile antibody, in addition to acting as a hæmolysin for sheep cells, forms a precipitate and fixes complement when mixed with an emulsion of these lecithin fractions of tissues containing heterophile antigen. The lipoid extracts are not antigenic, but can be made so by mixing with a suitable protein, the resulting antisera containing both heterophile antibodies and antibodies specific for the protein used (Landsteiner and Simms 1923). These haptens were apparently lipopolysaccharide in nature (Landsteiner and Levine 1925, 1927 ; but see also Renaux and Thomas 1942).

The human Group A substance, which in pure form is a non-antigenic hapten, has proved to be a viscous substance made up of polysaccharide units, partly hexose, partly N-acetylglucosamine, and a number of amino-acids (Goebel 1938, Landsteiner and Harte 1940, 1941, Morgan and King 1943, King and Morgan 1944). As we have indicated in Chapter 8, a number of bacteria contain the Forssman antigen or substances immunologically related to it. In *Sh. shigæ*, the Forssman hapten is associated with the lipopolysaccharide moiety of the somatic antigen (Meyer and Morgan 1935, Meyer 1938, Morgan and Partridge 1940). As Morgan showed, the hapten from *Sh. shigæ* is not antigenic, but can be made so by reunion with the protein moiety of the antigen (see p. 261). The Group A substance can in the same way be made powerfully antigenic by union with this *Sh. shigæ* protein ; and the resulting antigen, like the complete antigen of *Sh. shigæ*, stimulates the production of heterophile antibodies. This interesting demonstration, together with that of Landsteiner and Simms (1923), suggests a means whereby heterophile antigenic properties might be acquired by certain organisms, and suggests the underlying mechanism of a phenomenon observed by Holtman (1939), who induced the formation of heterophile antigens in *Salm. typhi* and *Salm. paratyphi B*, by prolonged subcultivation on media containing Forssman antigen (horse serum) or by growth in collodion sacs implanted in the peritoneal cavity of guinea-pigs. This phenomenon makes it clear, at all events, that the cultural history of bacterial antigens employed may be of great importance in the investigation of heterophile antigens ; and the demonstration that bacteria acquire Forssman antigens by contact with animal tissue, as Holtman points out, may have some bearing on the fact that the bacteria which are known to contain Forssman antigens are for the most part parasitic and may as a species have acquired the antigen by contact with the host's tissues.

The Forssman antigen of the pneumococcus is also related to a somatic antigen, but not, as in *Sh. shigæ*, to the dominant antigen of the virulent organism. The more recent investigations of Goebel and his colleagues (Goebel and Adams 1943, Goebel, Shedlovsky *et al.* 1943) indicate that it is a lipopolysaccharide, containing a high molecular weight fatty acid, an acetylated amino sugar and a second hexose. The polysaccharide is closely related to, if not identical with, the somatic " C " polysaccharide of the pneumococcus described by Tillett, Goebel and Avery (1930). It is noteworthy that an antibody to this C substance appears in the serum of patients in the acute febrile stage of infection

with pneumococci and a number of other bacteria (Tillett and Francis 1930, Ash 1933, Francis and Abernethy 1934, Abernethy and Francis 1937). The same kind of antibody can be induced in *Macacus* monkeys by infection with pneumococci, but not in rabbits or mice (Abernethy 1937). The antibody or "C-reactive protein," is unusual in many respects. It appears rapidly in the serum of the infected animal and develops with the inflammatory reaction, whether pneumococcal or otherwise; it persists only during the activity of the lesion, and in pneumonia disappears before the crisis; it precipitates with the C polysaccharide only in the presence of calcium ions, and is precipitated from serum by salts along with the albumin fraction (Abernethy and Avery 1941); it is antigenic, and antigenically distinct from the normal proteins of human or monkey sera, though the C-reactive proteins of man and monkey are antigenically similar (MacLeod and Avery 1941); and in the electrophoretic tube it migrates neither with albumin nor the β- and γ-globulins, but is an apparently new type of protein migrating with the α-globulins (Perlman, Bullowa and Goodkind 1943). This antibody, the "C-reactive" protein, is similar to one found by Löfström (1939, 1942, 1943, 1944), in human sera, which agglutinated with, and induced a capsular swelling reaction in, certain pneumococcal types. Its relation to heterophile antibodies is not clear. Lofström found that it was formed in the acute stages of non-infectious disease in which there was marked tissue destruction, and was able to induce its appearance by the injection, for example, of colloidal sulphur.

In the C-reactive protein we have therefore an example of an antibody-like substance which at first sight appeared to be specifically induced by an antigenic component of a bacterium, with which it reacted in an apparently orthodox manner, but whose production was found on analysis to be conditioned by the species of animal, and by a number of non-specific stimuli, including bacterial infections. It at least provides a firm factual basis for a hypothesis of a natural antibody formation which is independent of stimuli by the kind of antigens we have discussed in Chapter 7, and which may be independent of the mechanism of antibody-formation discussed in Chapter 50.

We may note that heterophile antigens and antibodies other than those of the Forssman type occur in animal tissues. Thus Deicher (1926) records that the injection of horse serum into man induces the formation of agglutinins not only for sheep erythrocytes, but also for those of the rabbit, which contain no Forssman antigen. The distinction of these agglutinins from Forssman antibody was confirmed by Schiff (1937) who demonstrated them in man following injection of rabbit serum, which also contains no Forssman antigen. There appeared to be two antigens concerned, one specific for rabbit erythrocytes, the other shared with those of the sheep, horse and ox. Graña (1944) records similar antibodies in patients with hydatid cysts, who have been injected with hydatid fluid. Brown (1943) found an additional thermolabile antigen in mouse tissues distinct from, but related to, the Forssman antigen. (For a discussion of an apparently heterophile antibody of yet another type, which characterizes the serum of patients with infectious mononucleosis, see Bernstein 1940).

Age and Natural Antibody Production.

We may note that normal hæmolysins and hæmagglutinins are absent from the blood of very young animals, and are developed during the process of normal growth (Hirszfeld 1926, Friedberger, Bock and Fürstenheim 1929). The same is apparently true of the natural antibacterial agglutinins (Kraus and Low 1899, Lüdke 1905, Braun 1909, Gibson 1930; see also Mackie and Finkelstein 1928, 1930). Both Rywosch (1907) and Sherman (1919) noted that the normal hæmagglutinins of the fowl did not appear in the chick embryo until the twenty-first day, though Rywosch observed lysins of *Bact. coli* as early as the fourteenth day. In this connection it may be noted that Polk, Buddingh and Goodpasture (1938) could find no complement in the chick embryo. It appeared suddenly in the newly hatched chicken, and gradually increased with age. Observations made by Bailey (1923) add a point of considerable significance. He also noted the absence of normal hæmagglutinins in the young chick, and their appearance during the normal

process of growth, but he also found that chickens failed to respond to immunization with foreign red cells until they had spontaneously developed some agglutinating capacity. The inability of the antibody-forming apparatus to respond effectively to an antigenic stimulus during the earliest period of life would seem to be a general rule. Thus, Blum (1932) and others have noted the failure of young infants to produce diphtheria antitoxin in response to the injection of toxoid. The antibody response of young rabbits to the injection of bacteria, erythrocytes, or of soluble protein antigens is poor (Freund 1930). Baumgartner (1934) found that production of agglutinins to *Salm. enteritidis* given intravenously to rabbits was not maximal until maturity was reached. The response in 50-day-old rabbits was poor, and moderate at 70 days. It is also noteworthy that antibody from the younger animals had a lesser "avidity" than that from the mature rabbit. Baumgartner (1937) later observed a similar age difference in the response to ovalbumin, and showed that the combining power of the precipitins produced increased with the age of the immunized animal.

In Chapter 7 we have given reasons for believing that antibodies are specialized serum globulins. It is therefore of particular interest to find that the serum of new-born animals is markedly deficient in globulin, particularly in euglobulin, that this deficiency is temporarily made good in certain species by the transfer of globulin from mother to young in the colostrum, and that the capacity for producing euglobulin from its own tissues is developed by the young animal at a later stage of growth (Toyama 1919, Howe 1922, Lewis and Wells 1922). Both Jameson, Alvarez-Tostado and Sortor (1942) and Polson (1943) record striking changes in the serum proteins of calves and horses after birth, as determined by electrophoretic analysis. Polson records an increase in protein concentration from 3·7 per cent. at birth, to 5·25 per cent. after 5 days' suckling. At 8 months the concentration was 6·8 per cent. At birth the predominant protein was albumin (65 per cent.) and the remainder mainly α-globulin. The β- and γ-globulins, with which, it will be remembered (Chapter 7), antibodies are associated, were absent, or present only in small quantities at birth, increased rapidly in the nursing period, and at 8 months together constituted 50 per cent. of the serum proteins. The appearance of the natural antibodies and the increase in serum globulin are closely correlated with one another (see Famulener 1912). Orcutt and Howe (1922) have observed the passage of natural agglutinins for *Br. abortus* from a cow to her calf in the globulins of the colostrum; and Timmerman (1931) has demonstrated the presence of agglutinins for the typhoid bacillus in human colostrum during the first 5 days of suckling.

Little is known of any association between genetic constitution and natural antibacterial antibodies. Irwin and Bell (1935) bred two lines of rabbits, one of high, the other of low resistance to *Br. suis*, and found that resistance was correlated with the bactericidal power of whole blood for the organism. The lethal power of the blood depended on the presence of bacteriotropins, which were specific for *Br. suis* in that they had little effect on *Br. abortus* or *Salm. enteritidis*; but the evidence does not permit us to decide whether it was the production of bacteriotropins, or a readier response to latent immunization by antigens identical with or similar to those of *Br. suis*, that was genetically determined.

The Origin of the Natural Antibacterial Antibodies.

It is clear, therefore, that during the normal course of its development, any animal will produce a number of natural "antibodies" differentiated from one another in possessing different specific combining groups. Some, like the α and β agglutinins in human sera, are formed as the result of an internal physiological disposition of the animal, and others in response to an external environmental stimulus, which we may or may not be able to attribute to a known antigenic substance.

The acceptance of the view that some of the natural antibodies that act on

bacteria may arise during the normal production of serum proteins, simply because of an accidental chemical affinity between certain of these proteins and certain bacterial antigens, does not involve the assumption that this is the usual method of production. It is much more likely that environmental stimuli play an important part. The most obvious of such stimuli is that provided by natural infection with the bacteria on which the natural antibodies are found to act. How does this conception of their origin accord with the available evidence ?

If we turn back to the observations of Bürgi, of Gibson, and of Lovell on normal agglutinins we at once meet with a difficulty. Can we really believe that such animals as the ox and the pig are infected during their relatively short lives with such a variety of organisms as *Proteus X*19, *Salm. typhi*, *Salm. paratyphi A*, *Salm. paratyphi B*, *Salm. enteritidis*, *Sh. flexneri*, *Sh. shigæ*, *V. choleræ*, and, doubtless, a host of other pathogenic organisms that are absent from the list only because they have never been tested ? We need not indeed postulate manifest infections. It is sufficient at some time or another for the animal to have carried the organism, presumably in the alimentary tract. Even so, so wide a bacterial experience seems unlikely, simply because we are not used to recognizing the carrier state for such a multiplicity of pathogenic species. It is, however, possible that oxen and pigs are in fact carriers of these organisms but that our cultural techniques are inadequate for their detection. Von Bunza (1937), for example, found *Salm. suipestifer* in none of 149 healthy pigs whose fæces he tested by orthodox methods of cultivation. Nevertheless, by a special technique, he was able to demonstrate its presence in 34 of the pigs.

But even if by the most fruitful methods of cultivation we were still unable to demonstrate the presence of bacteria corresponding to these antibodies, there is still the possibility that the stimulus was provided by the antigens of dead bacteria, or by materials containing a similar antigen. In defining an antigen we excluded administration by the digestive tract when demanding that it should give rise to the production of antibodies on injection into a suitable animal, because the antigen might be chemically altered while in the digestive tract, and we should in any case have no assurance that it would pass from the intestine into the tissues in an active form. But recent studies on oral immunization have made it clear that the antigenic components of dead bacterial cells do, in some cases at least, pass from the intestines to the tissues and stimulate antibody formation. It is at least possible that among the unlimited variety of other antigenic materials which gain access to the intestinal tract, some, under favourable conditions, may behave in the same way. Were this the case, there would be little cause for surprise if some few of the multiplicity of reactive groupings produced by an antibody-forming apparatus subjected to an infinite succession of widely varied stimuli should happen to show affinities to the antigenic groupings of certain species of bacteria. Nor need we limit the possibilities to the intestinal tract. There is good evidence that inhalation of antigenic material may result in an effective antibody response ; and under suitable conditions similar material may gain access to the tissues through the skin.

In a final analysis, antigenic specificity depends on chemical structure, and as we have seen in Chapter 8, widely different materials may have antigenic determinants in common. The fact that we discover natural antibodies by the use of a suspension of a bacterium in which we are interested does not necessarily indicate that they were formed in response to that bacterium. We know some-

thing of the detailed antigenic structure of certain groups of closely related bacteria but little with regard to the possible sharing of antigenic groups by biologically disparate species of living organisms. We must, then, accept the possibility that the antibodies which we detect in the blood of a high proportion of animals of a particular species, and which act specifically on bacteria A, B and C, may have been produced in response to infection with some other organisms, X, Y and Z. Lovell (1934) explored this possibility in the case of the natural agglutinins of young swine, and found in two instances that coliform bacilli isolated from the mesenteric glands induced, on injection into rabbits, the formation of agglutinins acting on certain bacilli of the *Salmonella* group. Later work has shown that the salmonella antigens are not uncommon among the coliform bacilli (see Chapter 30).

Ingalls (1937) records another instructive example. She found that the sera of normal adult rabbits contained agglutinins for a number of organisms present in the intestines and for other bacteria, including the pathogenic species, *Sh. shigæ*. The *Sh. shigæ* agglutinins were found to be identical with those for a normal inhabitant of the rabbit's intestines, an enterococcus, which apparently had a hapten in common with *Sh. shigæ*.

We have noted that antibodies of this type often show certain peculiarities. They tend to be present in low titre, and they tend to be very difficult to remove by absorption with the bacteria on which they act. So far as these particular antibodies are concerned the evidence appears to us to be definitely against the view that they are produced in response to natural infection.

This conclusion does not, however, apply to natural antibodies in general. Though the greater part of the evidence bearing on this problem has been obtained by studies of the kind outlined above, some of it has emerged from surveys of the normal antibodies present in the sera of human groups, living under different environmental conditions. Thus Silverthorne (1936) determined the nasopharyngeal carriage of meningococci in a group of human subjects, and found a high degree of correlation between the bactericidal capacity of the blood for meningococci, and their presence in the nasopharynx. It has sometimes been possible to correlate the results of such surveys with the associated epidemiological records, as in the studies on the distribution of diphtheria, or scarlatinal antitoxin referred to above (see, however, Peters 1940); and it has been shown quite clearly that the frequency of natural agglutinins for a particular bacterium, among a random sample of the human population living in a particular locality, is closely associated with the frequency of infections due to that bacterium in that locality. Examples are provided in the epidemiology of enteric infection (Chapter 69), of undulant fever (Chapter 75), and of certain virus diseases (Chapter 87 and 88).

A few surveys of a similar kind have been made in laboratory animals. Thus Bailey (1927) examined 81 rabbits taken from a laboratory stock among which cases of snuffles were occurring, due to infection with *Pasteurella lepiseptica*. Three rabbits were suffering from acute snuffles; cultures from the nose gave a copious growth of *Past. lepiseptica*, and agglutinins and complement-fixing antibodies were demonstrated in the blood stream. Nine had chronic snuffles; all of these showed the presence of *Past. lepiseptica* in the nares and agglutinins and complement-fixing antibodies in the serum. Three had suppurative lesions from which *Past. lepiseptica* was isolated; agglutinins and complement-fixing antibodies were demonstrated in their serum. Six showed no clinical symptoms of infection, but *Past. lepiseptica* was isolated from the nares; in all six agglutinins and complement-fixing

antibodies were found. Ten showed no symptom of infection and cultures from the nares yielded no *Past. lepiseptica*; in none of these could agglutinins or complement-fixing antibodies be demonstrated. Six rabbits were then taken, one of which yielded a scanty growth of *Past. lepiseptica* and showed the presence of complement-fixing antibodies to low titre, while the other five showed no evidence of infection. All six were infected with *Past. lepiseptica* by nasal instillation. All six became carriers without any symptoms of snuffles. The rabbit which was already infected showed a rise in titre of complement-fixing antibodies, and these antibodies appeared in each of the other five rabbits during the course of the succeeding three months.

There is then no doubt that the members of a herd, or population, submitted to a constant or recurrent risk of infection with a particular bacterium will tend to form antibodies acting on that particular organism in response to the stimuli provided by infection of varying severity; and the natural working of this mechanism will certainly play a large part in determining the frequency distribution of the antibodies concerned.

We must then accept the view that the naturally occurring antibacterial sensitizers, and perhaps also the natural antitoxins, may owe their origin to any one of four mechanisms: actual infection with the corresponding bacterium; infection with some other organism that shares a common antigenic component; the entrance to the tissues *via* the intestinal tract, or possibly by other routes, of non-living antigenic material capable of stimulating the production of an antibody with the active group in question; or the formation of such antibodies as a by-product in the normal functioning of the antibody-forming apparatus altogether apart from any specific external stimulus.

The Immunological Significance of the Natural Antibacterial Antibodies.

Do naturally occurring antibodies of the type considered above confer a relative immunity to the risk of natural infection, analogous to that conferred by the natural antitoxins? The evidence available does not allow of any but the most tentative answer. So far as it goes it suggests that there is sometimes a relation between the presence in the blood of a particular antibacterial sensitizer and a relatively high resistance to the corresponding bacterium; but that this relation is not a general one, and that many antibodies of this type are quite without effect on the resistance of the animal possessing them. This is not surprising. We have given reasons for believing that the natural antibacterial sensitizers acting on a single bacterium—even on the surfaces of a single type of bacterial cell—may be of several different kinds, and it seems not unlikely that some of these may have a protective value while others have not.

Kyes (1916) showed that, when virulent pneumococci were inoculated into the naturally immune pigeon, the organisms were rapidly withdrawn from the blood stream and phagocytosed by macrophages in the liver and spleen. Heist, Solis-Cohen and Solis-Cohen (1918) found that the whole blood of the pigeon was actively bactericidal for the pneumococcus while the whole blood of the susceptible mouse or rabbit was not. The serum of the pigeon was not bactericidal alone, indicating that the killing power depended on the leucocytes as well as on the constituents of the serum. That serum constituents are in fact concerned, and that among these constituents are specific antibodies, would seem to follow from the observations of Bull and McKee (1921), who studied the passive transfer of immunity from the normally resistant chicken to the normally susceptible mouse. They found that chicken serum would protect mice against virulent pneumococci of Types I, II and III; and that absorption of the chicken serum with Type I pneumococci removed

its protective power against Type I but not against Type II. Similarly absorption with Type II removed the protective power against this type, leaving the protective power against Type I.

Robertson and Sia (1924) found a marked inhibition of the growth of pneumococci in serum-leucocyte mixtures from the resistant cat or dog, but no such inhibition in similar mixtures from the susceptible rabbit or guinea-pig. More recently they have reported experiments which suggest that this bactericidal action is due to sensitization followed by phagocytosis (Robertson and Sia 1927). They sensitized pneumococci by prolonged contact with large amounts of the serum under test, and then determined the degree of phagocytosis by the leucocytes of various resistant and susceptible animals. They found that sensitization with serum from the resistant cat, sheep, pig and horse rendered the pneumococci susceptible to phagocytosis by the leucocytes of these animals, or by those of the susceptible rabbit or guinea-pig; while treatment with serum from such susceptible species as the rabbit, guinea-pig or man did not sensitize the pneumococci for the leucocytes of these animals, or for those from the resistant cat, sheep, pig or dog.

The actual number of sera from each species examined by Robertson and Sia was not large, and it would seem that their original conclusions require some modification, at least in regard to man. Thus, Robertson and Cornwell (1930), using serum-leucocyte mixtures, studied the presence of antibodies for various types of pneumococci in the serum of normal persons. All the sera examined showed the presence of antibodies for one or more of the serological types employed, but any given serum might be inactive against some types though active against others. It would seem, moreover, that the presence of antibodies against a particular type does not afford complete protection against infection with that type, since Robertson and others (1930) found that the serum of patients in the first 48 hours of an attack of lobar pneumonia often contained sensitizing antibodies for the infecting type of pneumococcus. Abdoosh (1936) studied the bactericidal power of the serum against gonococci in man and a large number of animal species. It was low in normal men and mice, poor in the guinea-pig. It was good in horses, oxen, sheep, pigs, goats, cats, monkeys, rabbits and rats, animals naturally insusceptible to the gonococcus. It is of interest to note that a similar degree of bactericidal activity was reached in man only 14 or more days after the onset of a gonococcal infection.

Some of the findings recorded in earlier sections with regard to the frequency distribution of various normal agglutinins make it very difficult to believe that they have any protective value. Thus somatic agglutinins for various organisms of the *Salmonella* group are frequently present in the blood of swine, cattle and sheep; but these species are relatively susceptible to infection with certain of these organisms (Lovell 1934). A particularly striking example of this kind of anomaly is afforded by the observation that the great majority of normal horse sera agglutinate the glanders bacillus to high titre, though glanders is bacteriologically a disease of equines (see Wilson 1934).

SUMMARY

(1) Antibodies of various kinds—antitoxins, agglutinins, bactericidal antibodies and so on—are frequently found in the serum of normal men and animals. The origin of these naturally occurring antibodies is still a matter in dispute; but it seems possible that they may arise in several different ways.

(2) The new-born animal, when born of a naturally immune mother, is endowed with a congenital passive immunity, due to transference of specific antibodies from the maternal blood through the placenta, or by way of the colostrum during

the early days of suckling. This, like other types of passive immunity, is of relatively short duration.

(3) Young animals from whose blood these congenitally acquired antibodies have disappeared and young animals in whom they are not present at birth often develop them with advancing years.

(4) There are reasons for believing that this production of antibodies is dependent on the activity of an antibody-forming apparatus that is imperfectly developed at birth, but reaches functional maturity at a relatively early period of life.

(5) It is certain that this apparatus, apart from any external stimuli, will form various antibodies—such as the normal hæmagglutinins or hæmolysins—which distinguish one animal species from another. It is possible that certain of the antibodies acting on bacteria or their products may be formed in the same way, as the result of a normal serogenesis determined ultimately by genetic factors.

(6) The more commonly accepted view is that these antibodies arise as the result of the response of the antibody-forming apparatus to external environmental stimuli, and that such stimuli usually consist of overt or latent infections with the bacterium in question. This view has been upheld particularly in relation to natural antitoxic immunity against diphtheria and scarlet fever, and in this regard there can be little doubt that it is correct.

(7) In the case of specific antibacterial immunity there are greater difficulties in accepting this hypothesis in its entirety. Samples of sera collected from a given animal species may contain antibodies active against a large number of different bacteria, and it seems difficult to believe that a single animal can have been infected with so many different organisms, some of which are not known to be natural parasites of the species to which it belongs. There are, however, good reasons for believing that some at least of the agglutinins or other antibodies found in normal men or animals have been produced in response to infection, overt or latent.

(8) It is possible that other forms of external stimuli may be concerned, such as (*a*) infection with a different species of bacterium, which shares a common antigenic factor with the bacterium with which the antibody in question has been shown to act, or (*b*) the absorption from the intestinal canal or through the lungs or skin of some antigenic material containing a similar reactive chemical group.

(9) The presence of natural antitoxin in the circulating blood is usually associated with an immunity to clinical infection, at least in the case of diphtheria and scarlet fever.

(10) The relation between the presence of antibacterial sensitizers and resistance to infection with the corresponding bacteria is very uncertain. It seems probable that some of these natural antibodies exert a protective effect.

CHAPTER 50

THE ANTIBODY-FORMING APPARATUS AND ITS REACTIONS

In the preceding chapters we have referred freely to the serum antibodies without any attempt to describe the mechanism by which they are produced. Any adequate description is, indeed, impossible. We know too little. It is, for instance, quite clear that the formation of antibodies is associated in some intimate way with the formation of the serum proteins, but we are largely ignorant as to how these proteins are produced, or where. The scanty data at our disposal with regard to the cells and tissues probably involved and the way in which they respond to specific and non-specific stimuli are, however, well worth considering; since they throw light on several problems of practical as well as theoretical importance.

The Site of Formation of Antibodies

Ehrlich's conception of antibodies was that they were shed "cell-receptors." The antigen gained effective contact with the cell by becoming anchored, through specific chemical groupings of its own, to specific chemical groupings on "side-chains" carried by the tissue cells. This theory seemed to imply, by logical extension, the view that antibodies were produced by those cells to which particular antigens, by reason of their chemical structure, were most likely to become attached —that an antitoxin, for instance, was produced by the cells that were most susceptible to the corresponding toxin. A further implication seemed to be that any cell in the body was endowed with the potentiality of forming antibodies, should antigens with suitable side-chains present themselves to it. It would be rash to say that the possibility of such a generalized distribution of function has been excluded, but the trend of opinion, especially in recent years, has quite clearly been towards a different conception, which would regard the antibody-forming apparatus as an integrated system of cells, together constituting a functional though not a structural entity. The evidence on which this view is based may be summarized as follows.

The Local Formation of Antibodies.—Experiments designed to demonstrate the local formation of antibodies, at or in the immediate neighbourhood of the site of inoculation, have given either negative or only suggestive results.

Römer (1901) recorded observations which he regarded as demonstrating the formation of anti-abrin in the rabbit's conjunctiva; and von Dungern (1902) injected crab-plasma into the anterior chamber of one eye of each of several rabbits and recorded, in one instance, the appearance of a precipitin for crab-plasma in the aqueous humour of the injected eye before its appearance in the blood serum. But these observations have never been confirmed; and, at least in the case of Römer's results, they are open to criticism on technical grounds (see Hektoen 1911). Similarly, the results recorded by Wassermann and Citron

(1905), who injected typhoid bacilli into rabbits intrapleurally and intraperitoneally, and compared the antibody titre of the local exudate and of the blood serum at various times thereafter, afford no convincing evidence of any formation of antibodies in the serous cavities. Hektoen (1911) conducted a very careful series of experiments on the immunization of dogs with rat or goat corpuscles. He was unable to obtain any evidence of antibody formation in the anterior chamber of the eye, in the pleural or peritoneal cavity, or in the connective or muscular tissue of the leg. In every case antibodies appeared in the blood, but there was no evidence that these were produced at the site of inoculation. The experiments of Walsh and Cannon (1938) suggest that antibody is formed locally in response to a direct application of antigen. The antibody content of the blood, and of organs after removal of the blood by perfusion, was measured after active immunization with salmonella bacilli. After intraperitoneal injections, agglutinins were found to be distributed evenly in the nasal mucosa, lungs and spleen, in each of which the ratio of tissue to serum titres was 1 : 10. After intranasal inoculation, the tissue-serum ratio in the nasal mucosa was lower than that in the spleen, and after simultaneous intranasal and intraperitoneal inoculations with different antigens, the splenic ratio was lower for the intraperitoneal than for the intranasal antigen and the nasal and lung ratios lower for the intranasal than for the intraperitoneal antigen.

Cannon and Sullivan (1932) record experiments which they regard as indicating the local formation of antibodies at the site of an intradermal injection; and Trawinski (1932) concludes, from his experimental findings, that the skin is involved in agglutinin production irrespective of the site of inoculation of the antigen.

Hartley (1940) injected a mixture of vaccinia virus and an aluminium hydroxide gel intradermally in rabbits. A nodule, in which the cellular reaction was predominantly macrophage, was produced at the site of inoculation. Extracts of the 4-day-old nodules contained from 2 to 10 times as much antibody as blood or other tissue extracts (see also Oerskov and Andersen 1938, DeGara and Angevine 1943). Burnet (1941), on the other hand, could find no evidence of local antibody formation in the skin of rabbits by direct injection of a variety of soluble and particulate antigens. However, in the case of the positive results the part played by the dermis may be ascribed to its richness in reticulo-endothelial cells; so that these observations are in accord with those described in the following section.

The Rôle of the Reticulo-Endothelial System in the Formation of Antibodies.

Hektoen and Carlson (1910) injected dogs with rat or goat corpuscles and bled them dry from the carotid artery during the latent period of immunization, before any rise had occurred in the antibody titre of the serum; immediately thereafter they restored their blood volume by transfusion from a normal dog. This procedure appeared to have, if anything, a stimulating effect on the subsequent antibody production, indicating that the injected antigen had been rapidly removed from the blood. This suggestion was confirmed in other experiments in which normal dogs were bled dry and transfused with blood from other dogs 3 to 48 hours after inoculation of the antigen. When the dose of red cells injected into the donor had been of the usual optimal amount the recipient showed no rise in antibody titre, indicating that no appreciable amount of antigen remained in the circulating blood even after so short an interval.

We need only recall the description of the clearing mechanism given in Chapter 47 to evoke the suggestion that the cells of the reticulo-endothelial system, which we know to be concerned in the removal of foreign particulate material from the blood stream, are also concerned directly or indirectly in the formation of antibodies.

The view that certain of the organs or tissues which we now group together under this system might be specially concerned in antibody formation is by no means new. Pfeiffer

and Marx (1898) stated that in rabbits, which were undergoing immunization against cholera vibrios, bacterial antibodies might be present in the spleen, the bone-marrow, and perhaps the lungs, in higher concentration than in the blood (see also Tsurumi and Kohda 1913, Cary 1922).

Deutsch (1899) studied the effect of splenectomy on the production of agglutinins and protective antibodies after intraperitoneal injection of typhoid bacilli into guinea-pigs, and found that splenectomy before the injection of the bacterial antigen had little or no effect on the subsequent antibody production, while splenectomy carried out 3 to 5 days after the immunizing injection led to a significant decrease in the concentration of antibodies. He added the interesting observation that, when the spleen was extirpated from a recently immunized guinea-pig and transferred to the peritoneum of a normal guinea-pig, anti-typhoid agglutinins appeared in the blood of the latter though to a relatively low titre. Luckhardt and Becht (1911) studied this question in greater detail. Dogs were injected intravenously with rat or goat corpuscles. Shortly afterwards the spleen was removed, emulsified, and injected into the peritoneum of a normal dog. The recipients showed the typical rise in the antibody titre of the blood serum. The animals from which the spleen had been removed after injection of the red cells produced hæmolysins, hæmagglutinins and hæmopsonins less rapidly and to a lower titre than did the control animals not submitted to splenectomy.

The experiments of Topley (1930) on agglutinin formation in rabbits gave analogous results, and afford the additional suggestion that, after minimal doses of antigen, the reticulo-endothelial cells do not release the antigen in an unaltered form. Rabbits received intravenous injections of killed paratyphoid bacilli in a dose of 10^5 bacilli per kilo. body weight. At varying intervals thereafter, 24 hours to 216 days, they were bled and killed. The spleen, emulsified in saline, was in each case injected into a normal rabbit. The serum from a rabbit killed 24 hours after the injection of bacilli contained no agglutinins. The rabbit that received the spleen tissue from this animal developed agglutinins to low titre, but the time relations of the response differed from those of the typical response to active immunization (see pp. 1106–1114) in several ways. The highest titre was reached earlier, and the agglutinins disappeared far more rapidly from the blood stream. Reactions of the same general type were noted in the normal rabbits injected with the spleens removed from the immunized animals after longer intervals. Moreover, these rabbits, when injected 21 to 62 days after receiving the spleen tissue with a minimal dose of the same bacilli, showed no evidence of the energetic secondary response (see pp. 1110–1114) which might have been expected if they had received a previous stimulus with unaltered antigen. These results are more compatible with the view that the histiocytes of the spleen themselves form antibodies or some intermediate product than with the view that they merely retain the antigen and afterwards liberate it in a form which provides an antigenic stimulus to other antibody-forming cells. DeGara and Angevine (1943) measured the antibody content of skin, bone marrow, liver, spleen and in some cases the lymph nodes, in rabbits inoculated intracutaneously with a single dose of streptococcal or pneumococcal vaccine. They found antibody was present in these sites before any antibody appeared in the blood, and persisted there after the blood levels had started to decline. They concluded that besides the organs naturally rich in macrophages, the inoculation site in the skin, and the local lymph nodes produced antibody, perhaps with the aid of macrophages accumulating therein as a result of the inflammatory reaction to the vaccine.

Scarff (1931) has recorded experiments suggesting that the reaction of the spleen to foreign blood corpuscles is different from its reaction to bacteria; and it may be that we should consider different antigenic materials—foreign cells, bacteria, antigens in solution and so on—in relation to different depôts of histiocytes, rather than antigens in general in relation to histiocytes in general.

The rôle of the reticulo-endothelial system in the production of antibodies has also been investigated by the method known as *blockade*, alone or combined with splenectomy. In this method large amounts of Indian ink or colloidal iron are injected intraven-

ously, with the object of engaging the activities of as large a quota as possible of the reticulo-endothelial system, and so rendering it less able to deal with a subsequent injection of antigenic material. The results recorded show some divergence. Bieling and Isaac (1921, 1922*a*, *b*) reported an inhibitory effect of blockade on antibody production, and several workers have obtained analogous results (Siegmund 1922, Gay and Clark 1924, Vanucci 1924, Jungeblut and Berlot 1926, Lewis and Loomis 1926, Meyer 1926, Tuft 1934). Others, however, have failed to detect any difference between the behaviour of normal and blockaded animals (Rosenthal and Fischer 1922, Fränkel and Grunenberg 1924, Ross 1926). Such discrepancies need cause no surprise. In the case of a system of cells so widely distributed throughout the body, the effectiveness of any method of blockade must vary according to the conditions obtaining in each particular case. Blockade that falls short of completeness may, as some authors have suggested (Standenath 1923), have a stimulating rather than a depressing effect. Philipson (1936) demonstrated the association of the reticulo-endothelial system with antibody formation in another manner. He measured the degree of blockade achieved after the intravenous injection of particulate matter by the diminution in the rate of absorption of congo red from the blood stream of rabbits, and found that whereas a primary injection of a typhoid vaccine had little blockading effect, a secondary injection 6 days later produced a blockade equal to that of large doses of Indian ink, and depressed the antibody level in the serum. One to two days later, the blockade effect diminished and at the same time there was a rise in the antibody content of the blood.

Other methods of injuring or disabling the cells of the reticulo-endothelial system have been utilized in attempts to study the part played by these cells in antibody production—the action of X-rays (Benjamin and Sluka 1908, Lawen 1909, Hektoen 1915, 1918, 1920), of thorium X (Hektoen and Corper 1920), and of radium emanation (Hektoen and Corper 1922), of benzene (Rusk 1914, Simonds and Jones 1915, Hektoen 1916), of toluene (Hektoen 1916*b*, Weaver *et al.* 1943) and of mustard gas (dichlorethyl sulphide) (Hektoen and Corper 1921). The results of these experiments, taken as a whole, lend support to the view that any procedure which severely injures the cells of the reticulo-endothelial system will markedly, or sometimes completely, inhibit the formation of antibodies. Their significance is, perhaps, rendered a little dubious by the fact that the doses required to produce a clear-cut inhibitory effect were of an order which makes it unlikely that their action was confined to the cells of the reticulo-endothelial system and the hæmopoietic tissues.

Sabin (1939) attempted to correlate the disappearance of a coloured azo-dye protein antigen from the reticulo-endothelial cells of the rabbit, with the antibody levels found in the serum. Her results suggest a connection between the two phenomena, but the antibody response in the few animals tested was too variable to permit any definite conclusions to be drawn.

The Rôle of Lymphoid Tissue in the Formation of Antibodies.

The association of lymph nodes with antibody formation was first clearly demonstrated by McMaster and Hudack (1935) who injected bacterial vaccines into the ears of mice, and after 2 hours, when some of the inoculum had passed *via* the lymphatic channels to the cervical lymph nodes, amputated the ear. In the early stages of the antibody response, the antibody content was highest in extracts of the nodes, and relatively low in the serum. The vaccine caused some inflammation in the lymph nodes, but the observed antibody levels were not due to an abnormal concentration of serum antibodies in the inflamed node, for when both ears were injected, each with a different vaccine, in each case the antibody levels attained were in the descending order—homolateral cervical node, blood serum, contralateral cervical node—though both cervical nodes were equally inflamed. McMaster and Kidd (1937) record similar results with vaccinia virus injected into the ears of rabbits, and Burnet and Lush (1938) with influenza virus given intranasally in mice, the highest antibody levels in this case being found in the mediastinal glands.

When subcutaneous injections of bacteria or bacteriophage are made into the leg of a rabbit, the early antibody response is highest in the popliteal node on the injected side (Burnet 1941). Murakami (1936) obtained higher titres in efferent lymph from nodes draining the site of injection of the antigen, than in the blood stream, but attributed the result to a concentration of serum antibodies in the inflamed node.

It is possible that the reticulo-endothelial cells of the lymph nodes are responsible for the local formation of antibody. Lymphoid tissue contains a number of "germinal centres," which are nodules of apparently primitive lymphocytes surrounded by mature lymphocytes, and are thought to be concerned in the genesis of lymphocytes. Hellman and White (1930), however, observed that the injection of antigenic material was followed by an increase, sometimes very marked, in the number of "germinal centres" of the lymphoid tissue of the spleen and the lymph nodes. Moreover, the "germinal centres" are not found in the fœtal tissues. According to Glimstedt (1936) they do not develop in the lymphoid tissue of young guinea-pigs reared in a sterile environment, but are plentiful in those that have been exposed to environments containing bacteria. The association of newly appearing centres with the stimulus of foreign antigenic material was confirmed by Österlind (1938) who found that diphtheria toxoid in the hind leg of a rabbit induced their formation maximally in the nodes draining the injected area, and that maxima of antitoxin formation, particularly in response to a secondary dose of toxoid, coincided with the maxima in numbers of germinal centres. Similar results were obtained by Ehrich and Harris (1942), using typhoid bacilli, sheep erythrocytes, and ovalbumin as antigens; in their hands the antibody maxima in efferent lymph and in the lymph nodes slightly preceded the maxima in germinal centres, whose increased numbers persisted some time after antibody levels were declining. More recently, Harris, Grimm, Mertens and Ehrich (1945) report that not only is the rise in antibody content of lymph from an immunized lymph node accompanied by a rise in the lymphocyte content, but that these cells contain substantially more antibody than the fluid itself. Moreover, since the cells can be made readily to yield antibody, but not to absorb it, it appears that the lymphocyte itself may be the actual site of antibody formation. There is, then, good, but not very extensive, evidence for the formation of antibodies in lymph nodes, and strong indications that tissues, which, though mesenchymal in origin, are not reticulo-endothelial in nature, may be concerned in antibody production. It should be noted that Burnet (1941) was unable to demonstrate any antitoxic response in lymph nodes to staphylococcal toxoid; he suggests that toxoid, being soluble, is not held up in the lymph nodes as effectively as particulate antigens are.

The Rôle of Other Organs or Tissues in the Formation of Antibodies.

It may be noted that the effect on antibody formation of the removal of other organs —unconnected with the reticulo-endothelial system—has been studied by various observers. The removal of the thyroid has apparently no inhibitory effect (Fjeldstad 1910, Hektoen and Curtis 1915, Ecker and Goldblatt 1921, Houssay and Sordelli 1921, Clevers 1921, Také 1923). An increase in antibody production has occasionally been recorded as a result of this procedure (Ecker and Goldblatt 1921, Houssay and Sordelli 1921, Clevers 1921). Hektoen and Curtis (1915) state that complete removal of the stomach or of the small intestine does not interfere with the formation of hæmopsonins or hæmagglutinins; simultaneous removal of the spleen and pancreas appears to have the same depressing effect on antibody production in dogs as removal of the spleen alone; adrenalectomy in dogs, at the height of the antibody curve, does not alter the antibody content of the blood serum; in rats, removal of one half of the liver appears to have no effect on the production of hæmolysin.

The Formation of Antibodies in Tissue Cultures.—A method which offers obvious possibilities for the study of antibody formation is that of tissue culture.

Carrel and Ingebrigsten (1912) cultivated fragments from the bone-marrow and lymph glands of guinea-pigs in the homologous blood plasma, and added to the cultures small

amounts of red cells from the goat, against which the serum of the guinea-pig showed no lytic action. Hæmopsonins appeared in the culture on the 3rd day, as judged by direct observation of the degree of phagocytosis. Hæmolysins were detectable on the 4th day, and had increased markedly in activity on the 5th. The hæmolysins could be specifically absorbed from the fluid by the usual technique. Ludke (1912) injected killed cultures of typhoid or dysentery bacilli into rabbits, removed fragments of the spleen or bone-marrow after 1 to 5 days, and cultivated them in homologous plasma. After 2 to 5 days' incubation he was able to detect lysins and agglutinins in the culture fluid. In a similar way he succeeded in producing hæmolysin for ox or sheep corpuscles. His results were for the most part negative when he added the antigenic materials directly to the tissue cultures. Przygode (1913, 1914), Reiter (1913) and Schilf (1926) have also recorded positive results. Meyer and Loewenthal (1928) record experiments in which they were able to demonstrate a significant rise in agglutinins in tissue cultures prepared from rabbits that had been inoculated with typhoid bacilli. The tissues examined were the spleen, the lymph glands and the milk spots from the omentum. The latter observation is highly significant, since the omental milk spots, in addition to fibroblasts, contain only cells of the reticulo-endothelial type. Subsequent workers have demonstrated antibody formation against a variety of antigens when the cultures were made from the tissues of already inoculated animals; and the results of adding the antigen after the establishment of the tissue culture *in vitro* have been uniformly negative (Hwon 1937, Parker 1937, Salle and McOmie 1937, Beard and Rous 1938). The reasons for the failure of *in vitro* immunization are not apparent, though Beard and Rous, who used a pure culture of Kupffer cells from the liver, note that the cultivated cells had lost their normal *in vivo* power of ingesting antigenic particles.

Conclusions with regard to the Site of Formation of Antibodies.—Taking the data as a whole the conclusions to be drawn do not seem to be in doubt in spite of minor discrepancies. There is ample evidence that the organs and cells which have been shown to be concerned in the clearing mechanism of the tissues are also concerned in some way with antibody formation. There is also evidence that lymphoid tissue may be concerned. It is clear that antibody formation is not the function of mesenchymal cells in any one organ of the body. Thus Buttle (1934), in short-term experiments with rabbits in the early stages of a secondary antibody response (p. 1110), was unable to interrupt the flow of antibodies from the tissues to the blood stream by extirpation of the liver and spleen, or by complete removal of the skin.

Of the precise part played by the cells of the reticulo-endothelial system we know little. We know that they remove from the blood stream particulate antigenic material, and probably similar material in colloidal solution. Do they themselves produce the corresponding antibodies, or do they merely retain the antigen temporarily, yielding it up in an altered or unaltered state to the tissue fluids, and thus passing it on to some other cells in which the actual antibody synthesis occurs?

Of the experiments outlined above, some of those dealing with the rôle of the spleen in antibody production, the results obtained by Meyer and Loewenthal with cultures from the omentum, and experiments with antibody formation in lymph nodes, suggest that the tissue cells themselves are capable of producing antibodies in the fully formed state.

The Response of the Antibody-forming Apparatus to Specific Stimuli

The Primary Response to a Specific Stimulus.—It will simplify discussion to consider first the response to the injection of an antigenic material directly into the blood stream. It will also be convenient to select an example in which the

antibody concerned is not present *ab initio* in the blood of the experimental animal employed. The production of flagellar agglutinins by the rabbit in response to a single intravenous injection of a killed suspension of *Salm. paratyphi B* affords a convenient illustrative example. Fig. 249 shows a typical reaction.

There is an initial induction phase, not shown in this particular diagram because the first reading after the injection of the antigen was taken on the fifth day. This induction phase usually lasts for 24 to 48 hours, by the end of which time agglutinin is usually detectable to very low titre (1 : 5 to 1 : 20). The titre then rises rapidly as shown in the figure, until about the 16th day. The time limits between which the maximum titre is usually attained may be put at about the 10th to 22nd day. It then falls, at first rapidly, then more slowly, agglutinins still being present in the blood 100 days after the inoculation. It will be noted that, in this chart, the titres are plotted as ordinates on a logarithmic scale, time as abscissæ on an arithmetical scale. Equal rises and falls in the curve represent not equal increments or losses of agglutinins but equal proportionate increases or decreases—for example, doublings or halvings of the amount present.

The Effect of Dosage.—As regards the relation between the dose of antigen administered and the amount of antibody produced, Table 81 sets out some figures for the particular case we are considering.

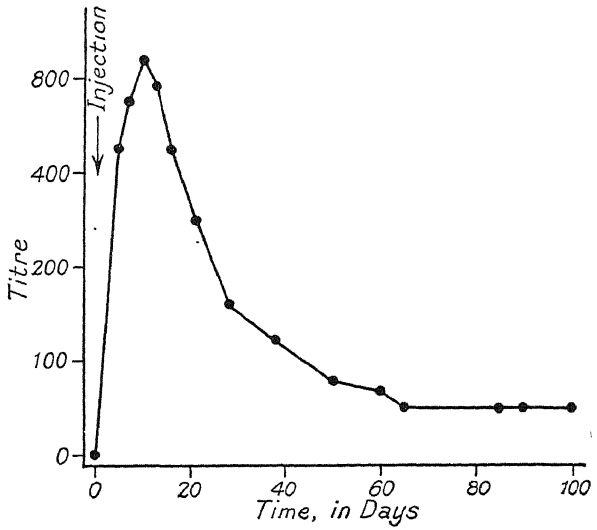

FIG. 249.

Production of agglutinins in rabbit after single injection of *Salm. paratyphi B.*

The minute dose of 10,000 bacilli per kilo. body weight, administered to rabbits varying from 1,380 to 3,750 gm., results in no detectable formation of agglutinins. When we increase the dose ten times we pass the threshold and obtain an average titre of 1 : 330. Over the range 10^5 to 10^8 bacilli a thousandfold increase in dose results in about a tenfold increase in titre—the critical student glancing at the numbers in the second column will not place too much reliance on the mean values recorded in the third. If we increase our dose still further we shall get still higher titres; but we shall be reaching the point where our inoculum attains an appreciable toxicity, and we shall, apart from this, be subject to the law of diminishing returns. However high we push our dose, up to the limit that will kill our rabbit, we are unlikely, after any single inoculation, to reach a titre of more than 1 : 10,000–1 : 20,000.

We may sum up in general terms by stating that there is a minimal threshold value, below which no response is obtained. Above this value the titre attained varies with the dose administered but in such a way that the increase in titre is relatively much smaller than the increase in dose required to produce it. Even-

TABLE 81

SHOWING THE MEAN VALUES OF THE HIGHEST TITRE OF FLAGELLAR AGGLUTININS IN SMALL GROUPS OF RABBITS INJECTED INTRAVENOUSLY WITH DIFFERENT DOSES (PER k.b.w.) OF *Salm. paratyphi B.*

10^8	3	3,540
10^7	3	1,860
10^5	6	330
10^4	4	0 [1]

[1] = no agglutination at a dilution of 1 : 4.

tually a point is reached at which further increase in dose results in little or no increase in antibody production.

In connection with the problem of dosage, we may note one antigenic substance, the acetyl polysaccharide of the Type I pneumococcus, of which only very small doses induce an antibody response (Avery and Goebel 1933, Enders and Wu 1934). Thus Downie (1937) found an effective immunizing dose in mice lay between 1·0 and 0·01 μg., while doses of 100 or 1,000 μg. were ineffective.

Variations in Response to Different Antigens.—Fig. 250 shows the effect of injecting into an animal (a dog) a particular antigen (rat corpuscles) against which it possesses a normal antibody (hæmagglutinin).

It will be noted that the immediate effect of the injection is to cause a fall in the normal antibody titre, followed by a rapid rise of the type depicted in Fig. 249. This *negative phase* is a characteristic result of injecting any large amount of antigen into an animal that possesses the corresponding antibody in its circulating blood.

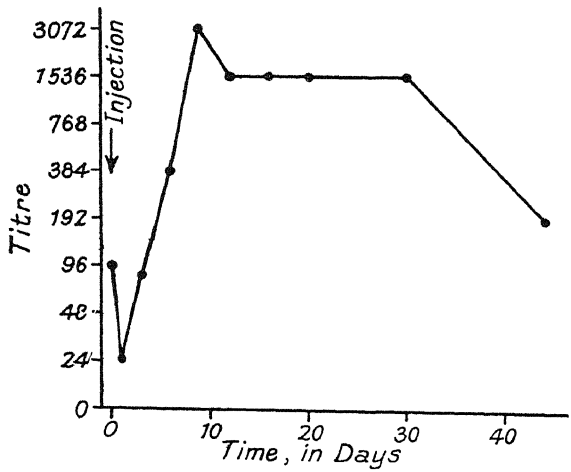

FIG. 250.

Production of hæmagglutinin in a dog after a single injection of rat corpuscles.
(After Hektoen and Carlson.)

The response to a single dose of an antigen in colloidal solution is illustrated in Fig. 251, which shows the course of precipitin formation in the rabbit following a single injection of horse serum.

There is a rather protracted induction period lasting for some 8 days, followed by a rise in antibody titre to a maximum about the 16th day and then a slower fall, till precipitin ceases to be detectable about the 37th day. It should be noted that this curve is not comparable, at a mere glance, with those given earlier in the chapter since the titres are plotted as an arithmetical not as a geometrical or logarithmic series. To make the

curve comparable with those describing agglutinin or hæmolysin production the logarithms of the number of precipitin units would have to be plotted as ordinates.

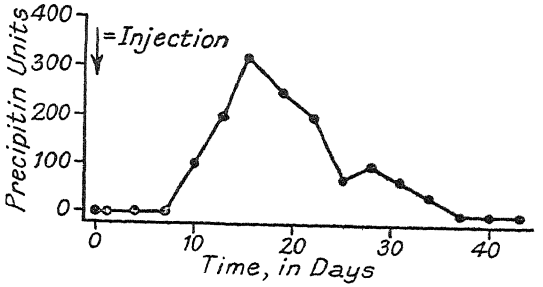

FIG. 251.

Precipitin production: response of a rabbit to single injection of horse serum.
(After Dean and Webb.)

The Response of the Antibody-forming Apparatus to the Simultaneous Injection of Several Antigens.

It is clear that the capacity of the antibody-forming apparatus must have some limit. The question at issue is at what stage that limit is reached. Will antibodies be formed as readily against two or three or n antigens, all injected at the same time, as against a single antigen? The answer is of considerable practical interest, since mass immunization against a multiplicity of diseases could be envisaged more cheerfully if syringes could be loaded on the blunderbuss principle. The evidence is conflicting.

There are records (Benjamin and Witzinger 1912, Huntoon and Craig 1921) which suggest that the injection of more than one antigen, simultaneously or in rapid succession, lessens the production of one or other of the corresponding antibodies. Corrigan (1925), and Hektoen and Boor (1931), on the other hand, have recorded results which indicate a far less restricted range of activity. The latter observers immunized rabbits by repeated intravenous injections of mixtures containing large numbers of different antigens, each in a relatively pure state. These included hæmoglobin from the ox, cat, dog, hog, horse, man, sheep and turkey, horse pseudoglobulin, serum albumin from chicken and man, egg albumin and other constituents. One of the mixtures contained 14 different antigenic constituents, the other 35. Precipitins were produced against almost all the antigens injected, and in most cases to high titre. In the particular case of antitoxins the careful work of Glenny and his colleagues (Glenny 1925*a*, Glenny, Hopkins and Waddington 1925, Glenny and Waddington 1926, 1928) makes it clear that the simultaneous injection of several antigens may considerably reduce the titre of anti-

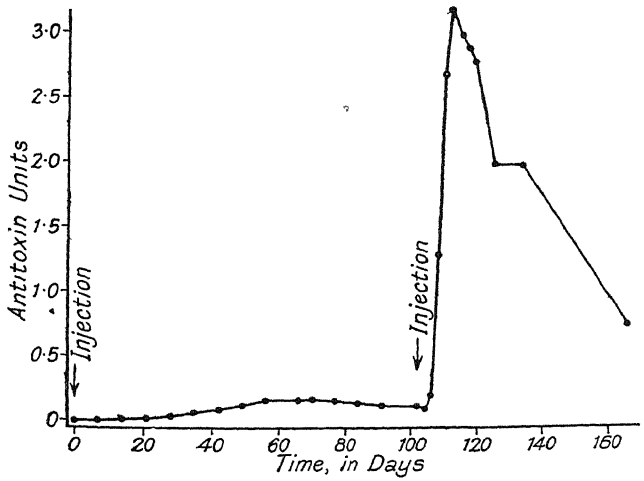

FIG. 252.

Antitoxin production in the horse: showing difference between primary and secondary response.
(After Glenny and Südmersen.)

toxin obtained. It seems likely, as Glenny suggests, that this " crowding out " effect is particularly prone to occur when any one antigen is present in great excess.

Bjorneboe (1941) immunized rabbits with vaccines containing from one to eight types of pneumococcus, which were given every second day for 8 months; the antibody production per type was the same for mixtures up to three types, and became progressively weaker as the number of antigens increased. It is noteworthy that when the " ceiling " values of serum antibody were attained, all the serum globulin appeared to consist of antibody. The separate antitoxic response of rabbits to mixtures of diphtheria, tetanus and staphylococcal toxoids (Ramon and Richou 1940) and of diphtheria and staphylococcal toxoids given intranasally (Sato and Kodama 1940) has been found to be similar to that following injections of the single antigens.

In man, a combination of two or more antigens is reported by some to have a synergic effect, each antigen being more effective in combination than alone. For example, synergic effects are recorded for mixtures of diphtheria and tetanus toxoids, with and without typhoid vaccines (Sacquepée, Pilod and Jude 1936*a*, *b*); for staphylococcal and diphtheria toxoids (Kodama, Sato and Hata 1940); for tetanus toxoid and typhoid vaccines (Ramon 1936, Maclean and Holt 1940; see also Grasset and Girdwood 1940, Fraser *et al.* 1943); for diphtheria and tetanus toxoids (Bigler and Werner 1941), and for these two toxoids and *H. pertussis* vaccine (Lapin, 1942). Neither synergic effect nor depression of antigenic stimulus was found in such mixtures as vaccinia and diphtheria toxoid (Stern 1935), diphtheria and tetanus toxoids (Jones and Moss 1937, Peshkin 1941), diphtheria toxoid and *H. pertussis* vaccine (Kendrick 1942, Sauer and Tucker 1942). With a mixture of *H. pertussis* vaccine, tetanus and diphtheria toxoids, Miller and Saito (1942) record a depression of the tetanus antitoxin response.

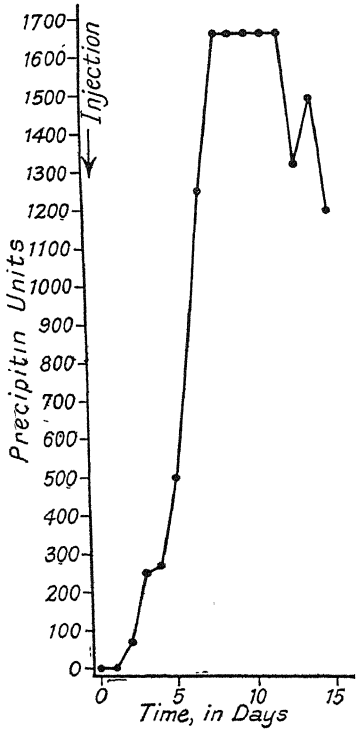

FIG. 253.

Precipitin production: response of a previously sensitized rabbit to a single injection of horse serum—secondary response.

(After Dean and Webb.)

With optimal doses of each constituent, and a total inoculum which is not unduly large, it seems probable that an effective response can be obtained against a reasonable number of different antigens, even if the titre of some or all of the corresponding antibodies is relatively reduced, and that in some cases there is a synergic effect in antigenic mixtures. From the practical point of view the problem will clearly differ according as we are attempting to induce an active immunity in man or animal, or to produce a high titre serum for passive immunization. In the former case a reduction in the antibody titre attained might be of minor importance, in the latter it would be a grave disadvantage. Each case, as it arises, should be subjected to experimental trial.

The Difference in Response to Primary and Secondary Stimuli.—Having considered the response of the antibody-forming apparatus to an initial injection of antigen we may inquire how it responds to repeated stimuli, and it will be convenient to take as our first instance the response of a horse to the injection of diph-

theria toxin, selecting an animal whose blood, at the time of the initial injection, is devoid of antitoxin. This particular reaction has been studied in great detail by Glenny and his colleagues (Glenny 1925*b*, 1931, Glenny and Südmersen 1921) and forms the basis of his insistence on the fundamental difference between a primary and a secondary response. Fig. 252 shows a typical example.

The primary injection is followed by an induction period of some 14 days, after which there is a very slow rise in the antitoxin content of the blood, reaching a low maximum of 0·16 units per ml. between the 9th and 10th weeks, and sinking slowly to 0·11 units by the middle of the 15th week, at the time of the second injection. The response to this second injection is of an altogether different character. Within 4 days a distinct rise in the titre of antitoxin is observable, and the curve then rises steeply to a maximum of 3·2 units per ml. on the 10th day, followed by a fairly rapid decline. It may be added that with repeated and increasing doses the antitoxin content of a horse's serum may be raised to well over 1,000 units per ml.

This difference in response to primary and subsequent injections of the same antigenic material is not limited to the production of diphtheria antitoxin, though it is particularly well marked in this case. Fig. 253, showing the response to an injection of horse serum in a rabbit which had previously been injected with that antigen, but whose precipitin titre had since sunk to zero, may be compared with Fig. 251 above.

The same holds true, in regard to the comparative titre attained, though not in regard to the prolonged induction period after the primary stimulus, when the antigenic material is particulate, as in the case of a bacterial suspension. Table 82 sets out the primary and secondary response of rabbits to the intravenous injection of 10^5 *Salm. paratyphi B* per kilo. body weight. It will be noted that the titres given are not the maximum attained but the average titre during the 50 days after inoculation. This value was selected because the curve of agglutinin titre after a secondary inoculation tends not only to rise higher than after a primary injection, but to remain high over a longer period.

TABLE 82

SHOWING THE AVERAGE TITRE OVER A PERIOD OF 50 DAYS AFTER PRIMARY AND SECONDARY INJECTIONS INTO RABBITS OF 10^5 *Salm. paratyphi B* PER K.B.W.

Rabbit.	Primary Average Titre.	Interval between 1st and 2nd Injections.	Secondary Average Titre.
R11	280	147 days	2,720
R19	37	147 ,,	1,720
R25	130	147 ,,	430
R30	130	133 ,,	1,230
R31	91	133 ,,	1,230
R33	110	133 ,,	2,010

The difference between the primary and secondary response is sufficiently obvious and needs no comment. With very small doses there may be no detectable primary response, antibodies appearing first after the second or later injection of a bacillary suspension. An illustrative example is given in Table 83.

Burnet (1941) has emphasized a distinguishing feature of the secondary response

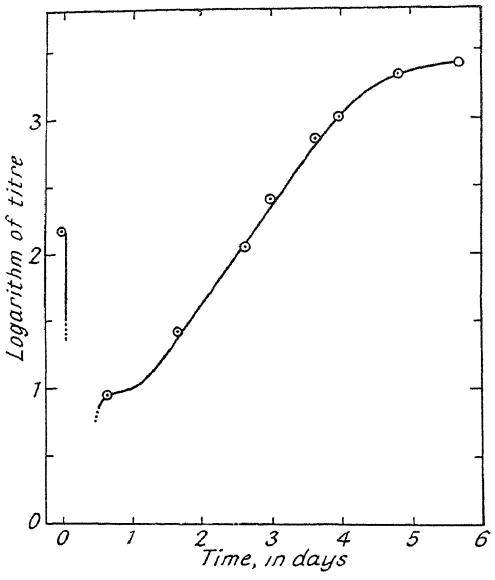

FIG. 254.

The secondary response of an immune rabbit to a single large intravenous dose of staphylococcal toxoid.

(After Burnet 1941.)

that is especially obvious when the stimulating dose of antigen is given intravenously. He studied the secondary response to staphylococcal toxoids, herpes virus and a bacteriophage, and in each case found that after a delay of 1 to 2 days, the antibody content of the serum increased exponentially with regard to time, until the maximum level was approached, when the rate of increase in antibody-content gradually diminished to a low value. In Fig. 254, for example, where the staphylococcal antitoxin content of the serum is plotted logarithmically, the curve is practically linear from the 2nd to the 4th day, after which it tends to the horizontal.

The tendency for the antibody titre to be maintained at a high level for a longer time after secondary and subsequent responses than after a primary response is illustrated in Fig. 255, showing the response of a rabbit to three widely spaced injections of *Salm. typhi*, Fig. 256, showing the response of an uninoculated person to an injection of typhoid vaccine, and Fig. 257, showing the response of a previously inoculated person to the same antigenic material.

R47 . . .	0	28 „	0	92 „	0

It must not be supposed that the differences between a primary and secondary response are always so clear-cut as those depicted here. The curves may, however, be regarded as giving a true picture of the kind of differences observed. It will be noted in Figs. 255 and 256 that the primary response may be quite brisk and result in a high titre of agglutinins. This, for instance, is the usual experience as regards the production of H agglutinins in response to the injection of an optimal dose of flagellated bacilli.

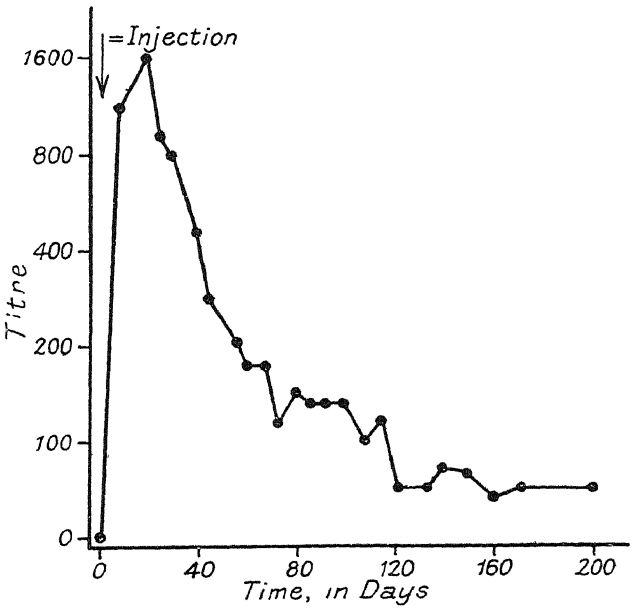

FIG. 256.

Agglutinin production: response of an uninoculated person to a single injection of typhoid vaccine.

We have noted that increases in the dose of antigen administered at a single injection are subject to the law of diminishing returns: in just the same way the repetition of injections, beyond a certain number, is usually found to produce less and less effect with each successive dose. When the titre of a particular antibody has been forced up to a certain level, which varies widely with the nature of the antigen employed and the responsiveness of the animal injected, it becomes impossible to induce any further rise in the concentration of antibody in the circulating blood.

Fig. 258 shows the effect of repeated subcutaneous injections of typhoid bacilli in the rabbit (Goldberg 1901). It will be noted that each successive injection raises the agglutinin titre, but that the increments tend to become proportionately smaller and smaller, the last injection on the 35th day producing a relatively trivial effect.

The importance of the secondary response (the " injection de rappel " of the French workers, the " boosting dose " of the American), in practical immunology must be emphasized. The primary stimulus apparently " conditions " the antibody-forming apparatus in such a way that a later stimulus from the same antigen induces a rapid and copious outflow of antibodies into the blood.

The study of antitoxin response to the immunization of man by diphtheria toxoid (see, for example, Jones 1938, Chesney 1939, and Chapter 61) and tetanus toxoids has thrown some light on the time relations of the primary and secondary responses. We may summarize the findings as follows: Both the serum antibody response and the " conditioning " produced by a single dose of toxoid may be low; large single doses are better than small. Two primary doses are better than one and the response is more effective as the interval between increases from 2 to 6 weeks. The response to a second dose at 6 weeks often has the marked character of a secondary response. Nevertheless, the " conditioning " process has not reached its maximum, for if a third dose is given 2 to 12 months later, the antibody level rapidly rises to a new and higher peak, and declines proportionately slowly. The same applies to immunization against tetanus (see Bergey 1934, Sacquepée and Jude 1937, Boyd 1938, Sacquepée, Pilod and Jude 1938, Marvell and Parish 1940, Peshkin 1941, Evans 1943). Schutze (1941) records an experiment in which mice were immunized with two doses of typhoid vaccine, one group at an interval of one week, a second at an interval of four weeks. The titres in the second group were 50 per cent. higher than in the first.

It is a common observation that the response to an antigen of an animal whose serum already contains a low level of specific antibody is greater than that of animals without serum antibody. Jensen (1937), for example, employs the relation between the two to group children in an ascending scale of immunizability to diphtheria according to the antitoxin levels in their blood (see also Flood 1930). However, absence of circulating antibody does not necessarily indicate absence of a " conditioned " antibody-forming apparatus. Thus, marked secondary responses to diphtheria toxoid can be evoked in children with little circulating antitoxin, 5 years after immunization (see, for example, Volk, Bunney and Tripp 1943).

The Enhancement of Response to an Antigenic Stimulus.

The possibility of enhancing the antibody response to a given dose of antigen has been explored by immunologists for many years. Among the numerous procedures devised to this end we may note two kinds—enhancement of response by variation in the mode or route of inoculation, and enhancement by the addition of adjuvant substances to the antigen. With regard to the route of immunization, it is generally held that antigens in the form of large particles, like bacteria or animal erythrocytes, are most effective when given intravenously (see, for example, Marinelli 1937) while soluble antigens are best given into the tissues. If a soluble antigen is attached to coarsely particulate matter, it may be most effective by the intravenous route (Freund and Bonanto 1941). A probable cause of the relative inefficacy of intravenously injected soluble antigens is their rapid elimination from the body. The same factor probably diminishes the stimulus of antigens injected into the tissues, for most of the procedures that increase antigenicity appear to act by hindering the release of antigen from the injection site.

Variation in the volume of the inoculum.—The experiments of Hartley (1935) indicate that the total volume of an immunizing injection, as well as its content in antigenic material has a significant influence on the antibody response. A series of guinea-pigs were injected with a constant dose of diphtheria toxoid made up in a total volume of 0·5 ml. or 5·0 ml of saline. In repeated tests it was found that the animals receiving the larger volum

gave a far better immunizing response. Timmerman and Brandwijk (1936*a*, *b*) confirmed Hartley's results. Schmitz (1938), however, repeated the test in medical students, and found no difference either in antitoxin response or in the rate at which antitoxin disappeared from the blood.

Dispersal of the inoculum through the tissues.—A stimulation of response resembling that of Hartley (1935) may be achieved by sub-dividing a dose of antigen into several smaller doses and injecting each into different sites in the animal. The response is greater than that produced by the whole dose administered singly (Ramon, Lemetayer *et al.* 1937, Miles and Pirie 1939).

The addition of adjuvants.—Adjuvants are usually intended for injection into the tissues, and are for the most part mildly irritant substances. Alum is one of the most widely used adjuvants. It was introduced by Glenny and his colleagues (Glenny *et al.* 1926) for improving the antigenicity of diphtheria toxoid, but has since been applied to other toxoids and to bacterial vaccines like those of *H. pertussis* (Chapter 74). Aluminium hydroxide is also effective (Hektoen and Welker 1933). Other successful adjuvants are lanoline in oil, cholesterol, salts of calcium and magnesium (Ramon *et al.* 1935); tapioca (Ramon 1937, 1939, Schmidt and Steenberg 1936); bacterial products like typhoid vaccine (Ramon 1936), staphylococcal toxin (Burky 1934, Swift and Schultz 1936); tubercle bacilli (Freund and McDermott 1942); serum containing heterophile antibodies (Kalinin *et al.* 1935). Both Glenny and Ramon attribute the action of alum and tapioca respectively to the stimulation of tissue lesions, from which the antigen is slowly liberated, thus providing a prolonged and continuous antigenic stimulus.

The lesion produced by a single injection of alum-precipitated diphtheria toxoid is apparently the chief source of antigen for some time after its formation. Thus Blagowechensky (1938) excised the lesion made by alum-toxoid at varying intervals after its formation in the skin of guinea-pigs and found that, within a period of 10–20 days, the degree of immunity reached depended almost entirely on the length of time the lesion had remained in the body.

The adjuvant effect has also been attributed to the high absorptive capacity of the substances employed. Aluminium hydroxide, for example, will absorb proteins *in vitro* (Hektoen and Welker 1933, Cohen and Mosko 1943, Holford, Ludden and Stevens 1943). Faragó and Ujhelyi (1942) injected groups ofguinea-pigs with diphtheria toxoid alone, with toxoid and $Al(OH)_3$ in the same injection sites, and with toxoid and $Al(OH)_3$ in different sites. The average antitoxin responses in units per ml. after four weeks were 0·005, 0·4 and 0·02 respectively. In the last group the toxoid was apparently absorbed by the separately formed $Al(OH)_3$ lesions, since lesions were antigenic when transplanted into normal guinea-pigs (see also Westwater 1940). It is in this case impossible to decide whether the *in vivo* absorption of toxoid was due to the $Al(OH)_3$ or to the cells of the lesion it induced. Ramon (1936, 1938) holds that the inflammatory response to the adjuvant is paramount in the adjuvant effect (see also Schmid 1938*a*) and on this basis devised a method of " concentrated immunization," in which small amounts of antigen are injected 4 or 5 times daily in the same site for periods of up to three weeks. By this means an inflammatory lesion is rapidly produced, into which toxic antigens may be injected without inducing a general toxæmia. In all cases the final antigenic response to this procedure was greater than that to the same total dose given in one injection. The inflammation was non-specific in its action, the response to tetanus toxin, for example, being increased by injection into a site inflamed by another antigen (Ramon, Lemetayer *et al.* 1937).

Fats are employed as adjuvants, and also for the purpose of modifying the toxicity of certain antigens (see Chapter 70). Ramon, Richou and Staub (1937) emulsified living *C. diphtheriæ*, *Staph. aureus* and *B. anthracis* in lanoline, and on subcutaneous injection obtained in the first two cases good antitoxic immunity, and with *B. anthracis* a high antibacterial immunity. Since the bacilli alone had no such effect they concluded that the lanoline allowed a local multiplication of the bacilli, production of toxins, a detoxication of toxins by the animal tissues without destruction of antigenicity, and a gradual release

of antigen from the injection site. Freund and his colleagues used lanoline to improve the antigenicity of heat-killed tubercle bacilli, and found that the size of the immune response depended on the size of the local lesion, which consisted of a non-necrotic monocytic reaction with fibrous encapsulation. The oil-tubercle bacillus mixture itself proved to be an active adjuvant for other antigens—horse serum, avirulent pneumococci, diphtheria toxoid and *Salm. typhi* (Freund *et al.* 1940, Freund and McDermott 1942, Freund and Bonanto 1944; see also Landsteiner and Chase 1942, Friedewald 1944).

We may say then that the antibody response to certain antigens injected into the tissues may be increased by methods which appear to diminish the rate of antigen release from the injection site. In the light of our discussion on the formation of antibody in the skin and lymph glands we cannot exclude the possibility that the local tissue reaction to some adjuvants includes cells capable of antibody formation, or that adjuvants act by increasing the number of antibody-forming centres in other parts of the body. In Hartley's (1940) experiments, for example, antibody was apparently formed in a predominantly macrophage nodule induced by $Al(OH)_3$ (p. 1102). Moreover, bacterial substances of the kind that have an adjuvant action on other antigens have also been shown to stimulate the formation of the germinal centres in lymphoid tissue (see p. 1105).

The Negative Phase.—Just as the injection of a considerable dose of a particular antigen into an animal that possesses a corresponding normal antibody may result in a temporary decrease in the concentration of that antibody in the circulating blood, the injection of a large dose of antigen into an animal that has already developed a certain concentration of antibody in response to earlier injections may be followed by a well-marked negative phase, which is usually followed in its turn by a rise in titre above the previous level. An illustrative example is afforded by the response of an immunized rabbit to two injections of horse serum, given intravenously at an interval of 5 days (Fig. 259). The importance of avoiding this negative phase in therapeutic immunization has been emphasized particularly by Wright and his co-workers (Wright 1909), though others maintain that in these circumstances there may be little diminution in the total immunity.

Schütze (1939), for example, infected mice with a dose of *Salm. typhi-murium* sufficient to kill 50 per cent. of the animals in about 14 days. The injection of four substantial daily doses of a specific vaccine of proved efficacy, beginning on the second day of the disease, did not increase the average mortality or the average time to death of the mice that died; in some experiments the vaccine appeared to save some of the mice.

Here the immunization of animals with an already established infection increased neither the severity nor the fatality of the disease. It must be remembered, however, that even though similar results were to follow tests of this kind with other infections, there may be conditions in which the negative phase is deleterious. In practice we are often concerned with the dangers of immunization of a herd that has been exposed to an infection, and that contains individual members who are invaded, but not yet infected, by the causal organism. In this case, a disturbance of the immune response may affect another perhaps more delicately balanced issue, namely the destruction or establishment of the invading organisms in the tissues of the host; and immunization might be followed by an increase of morbidity within the herd.

The diminution of circulating antibody in the negative phase, however, has implications other than a temporary depression of specific immunity in the animal. The newly injected antigen presumably combines with the antibody, and it is pertinent to inquire whether the antigen is modified by its union with antibody

Olitzki (1935) succeeded in suppressing the antigenic stimulus of a bacterial vaccine

in rabbits, either by preliminary lysis of the bacteria and saturation of the contained antigens with homologous antibody, or by a preliminary saturation of the surface antigens of the whole bacteria with antibody and a simultaneous injection of an excess of antibody into the test animal. This " blanketing " effect of antibody on antigenicity is of considerable importance in such procedures as immunization against diphtheria by the " combined method," in which antitoxin and toxoid are given at the same time, the one to provide an immediate passive immunity, the other as the primary stimulus for a more lasting active immunity. It is clearly desirable that the primary stimulus should be effective as early as possible in order that active immunity is established before the passive immunity has disappeared. It is, of course, impossible to measure the active antibody response to the primary dose of toxoid in the presence of the high concentration of passively administered antibody, but its effect on the antibody-forming apparatus can be estimated by the magnitude of the response to a second injection given some time later. If it is of the magnitude of a " secondary response," we may conclude that the primary dose has been effective. The results of a number of tests in man and animals are to some extent conflicting, but there is little doubt that if large doses of antitoxin are given, the toxoid may be partly blanketed and the development of active immunity delayed and inhibited to a variable degree (see Downie *et al.* 1941). The problem is fully discussed in Chapter 61. but we may note here that the blanketing effect is less apparent when relatively insoluble antigens are used, alum precipitated toxoid being more effective than fluid toxoid (Gundel and König 1938, Phair and Root 1942), and that by careful spacing of the subsequent doses of toxoid, the interval between declining passive and increasing active immunity may be made relatively small. The same considerations hold in combined active and passive immunization with tetanus toxoid and antitoxin (Ramon 1938, Cooke and Jones 1943, Gold and Backers 1943).

The Response of the Antibody-forming Apparatus to the Administration of Antigens otherwise than by Injection into the Tissues.

In defining the properties of an antigen on p. 194, it was stated that it should stimulate the formation of an antibody when introduced *parenterally* into the body. This caveat was included in the definition because administration *via* the intestinal tract does not ensure the passage of the antigen to the tissues in an unaltered and effective form. It may be broken down by the digestive enzymes. If it is not acted on by them it may never pass through the intestinal mucosa. Whether, in fact, any particular antigenic material administered by this route reaches the tissues in an unaltered form can only be determined by direct experiment. The available evidence suggests that some bacterial antigens, but not all, induce the formation of specific antibodies when administered by the mouth.

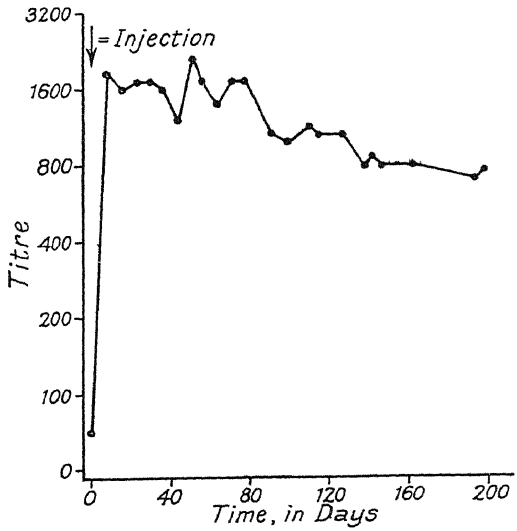

FIG. 257.

Agglutinin production: response of a previously inoculated person to a single injection of typhoid vaccine.

Thus, the administration *per os* of killed suspensions of flagellated bacilli of the typhoid-paratyphoid group results in the production of somatic (O) agglutinins, but flagellar (H) agglutinins are either not produced at all, or only to low titre (Pijper and Dau 1930, Greenwood, Topley and Wilson 1931). The same difference between the formation of H and O agglutinins appears to hold in the case of the cholera vibrio (Pfeiffer and Lubinski 1930). Dysentery bacilli, which are non-flagellated, induce the formation of somatic agglutinins when administered by the mouth (Kanai 1921, Otten and Kirschner 1927); and it is probable that analogous effects are produced by many other bacterial cells (see for instance Ross 1926, 1930, 1931, 1932, 1934, Downs and Bond 1937, Moor and Brown 1937, Torikata and Imaizumi 1938). It appears that the Vi antigen of the typhoid bacillus is ineffective by the oral route. Guarnacci (1939), for example, obtained low H and O titres in 68 per cent. of 227 persons given an oral vaccine of a (Vi + O) strain, but no Vi agglutinins.

In all cases it would seem that administration *per os* is far less effective than inoculation into the tissues, in the sense that much larger doses have to be given and the antibody titre attained is usually lower.

As regards other routes of entry, Stillman (1927, 1930) has shown that protective antibodies are produced in rabbits after the administration of living pneumococci by inhalation, but here we may be dealing with an active infection and consequent tissue invasion by living bacterial cells.

The intranasal application of diphtheria toxoid, by instillation, insertion on pledgets

of cotton wool, or as an atomized mist (Jensen 1937, Bousfield and King-Brown 1938, Fraser *et al.* 1940, Kodama, Sato and Hata 1940, Sato and Kodama 1940, Sordelli *et al.* 1942) acts as an effective stimulus to antitoxin formation, though less effective than injection into the tissues. Sordelli and his colleagues (1943) tested a number of antigens by the nasal and subcutaneous routes, and noted that *Salm. typhi* was ineffective by the nose; and that compared with subcutaneous injection a *Br. suis* endoantigen was less effective, staphylococcal toxoid equally effective, and tetanus toxoid more effective by the nasal route. Antibody response to intranasal vaccines of the influenza virus has also been demonstrated (see Chapter 88).

It seems justifiable to conclude that the administration of non-living antigenic material by various routes other than directly into the blood stream or tissue spaces will often result in antibody production, but that none of these alternative routes is usually either so certain or so effective.

The Nature of the Substances that stimulate Antibody Production.

In the preceding discussion we have been concerned with antigens of the chemically complex type, ranging from purified proteins to crude suspensions of bacteria or other cells. We have discussed in Chapter 7 the validity of the hypothesis that only proteins or protein-containing substances can induce an antibody response when injected into the tissues. It is clear that protein-free derivatives of fully antigenic substances not only act as haptens, but in some cases are themselves fully antigenic. There can be no doubt of the validity of Landsteiner's broad distinction between complete antigens and haptens, or of the association between decreasing chemical complexity, or molecular size, and a progressive loss of antigenic function; but it is not possible to predict at what stage in the degradation of a given antigen the complex will lose its full antigenic powers. In this connection it is instructive to consider the main type-specific antigen of the pneumococcus.

All the early studies on the purified polysaccharide components isolated from various bacteria, and in particular from pneumococci, suggested that these substances had the properties of haptens, and induced no immunizing or antibody-forming response when injected into the tissues. But observations have since accumulated which are difficult to reconcile with such a view.

Schiemann and Casper (1927) reported that the purified specific polysaccharide of the Type I pneumococcus, when injected into mice, produced an active immunity against living Type I pneumococci, but not against other types. They noted that this immunity was induced by the injection of small, but not of larger, doses. Schiemann (1929) recorded the immunization of mice by the injection of Type II pneumococcal polysaccharide, and noted that the blood of these immunized mice contained protective antibodies; though he was unable to demonstrate antibody production in rabbits. Francis and Tillett (1930) recorded observations suggesting that persons who were given repeated intradermal injections of the purified polysaccharide of Type I, II or III pneumococcus, developed a specific local response which took the form of an immediate wheal and erythema; and that this response was associated with the appearance of specific antibodies in the blood. Similar observations have been reported by Finland and Sutliff (1932) and by Zozaya and Clark (1932). Zozaya and Clark (1933) recorded the immunization of mice with polysaccharide fractions from Types I, II and III pneumococci, and noted that small doses were more effective than larger ones; but their results were irregular except when the polysaccharides were adsorbed on collodion particles or on carbon.

Later studies by Avery and Goebel (1933) have thrown further light on this question. They were able to show that the Type I pneumococcal polysaccharide, as it occurs in the bacterial capsule, possesses acetyl groups. These groups are lost during the separation

and purification of the polysaccharide by the methods which have been commonly employed. The acetylated form was found to induce active immunity in mice, when it was administered in small, but not in large doses. It did not induce antibody production in rabbits. Analogous results have been recorded in relation to other bacteria. For example, in *Salm. typhi* and *Br. melitensis* the lipopolysaccharide O-substance is fully antigenic; whereas in *Sh. shigæ* the antigenicity of the O-substance is lost when the association between the polypeptide and lipopolysaccharide moieties of the molecule is destroyed (Chapter 8).

The Response of the Antibody-forming Apparatus to Active Infection

The examples given above all refer to the response of the antibody-forming apparatus to the experimental injection of non-living antigenic substances. We may close this section with a few examples of its response to natural infections of the clinically obvious type. For simplicity we may confine our attention to acute infections, noting, however, that in the case of subacute and relapsing diseases, such for instance as tuberculosis, there is evidence that the antibody titre fluctuates as the infection varies from quiescence to activity.

As a typical example of an antibody curve during the course of an acute febrile infection we may take some of the numerous observations that have been made on patients suffering from typhoid fever. Figs. 260 and 261, constructed from data recorded by Jörgensen (1905), show the fluctuations in typhoid agglutinins during a typical attack of the disease, and during the terminal stage of a primary attack and the two relapses which in this case immediately followed it. The clinical course of the disease is, in each case, indicated by the fluctuations in temperature. It will be noted that, in the second of these cases, the agglutinin response during the primary attack was unusually feeble.

The Response of the Antibody-forming Apparatus to Non-Specific Stimuli.

Since the serum antibodies react specifically with their corresponding antigens it is natural to suppose that they will be formed *de novo* only in response to the specific stimulus provided by the introduction into the tissues of the antigen concerned. In making this supposition we must, however, be very careful to limit its implications. We must recollect, as has been emphasized in Chapter 8, thatwe are concerned with chemical substances, and not with particular species of bacteria or particular types of cell. We know that certain antigens are shared by several bacterial species; and the production, in response to the introduction into the tissues of one bacterium containing antigens a and x, of antibodies acting on another bacterium containing the antigens b and x is, in so far as it depends on the production of antibody X, a strictly specific response in the only sense with which we are here concerned. With these limitations, our supposition is in accord with all the recorded facts. The available literature contains no instance in which the introduction into the tissues of a substance of known chemical constitution has led to the production *de novo* of an antibody reacting specifically with a second substance, the chemical constitution of which bears no relation to that of the first.

If we turn to the production of a normal antibody in increased amount, a rise in the titre of an antibody previously produced in response to a specific stimulus, or the reappearance of such an antibody after the titre has fallen to zero, it is clear that our supposition no longer holds on *a priori* grounds. There would be nothing remarkable in an antibody-forming apparatus that had once produced, and possibly stored, a particular antibody, turning that antibody into the circulation anew, or in greater amount, in response to some non-specific stimulus which increased the activity of the apparatus without directing it into any particular channel.

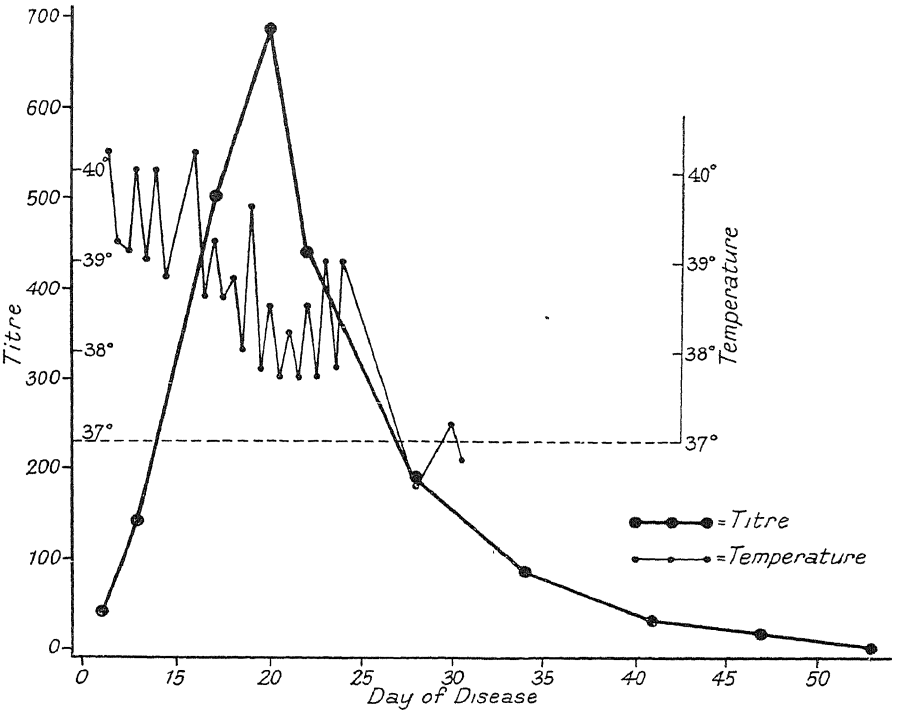

FIG. 260.

Rise and fall of agglutinins in blood of patient during an attack of typhoid fever.
(After Jörgensen.)

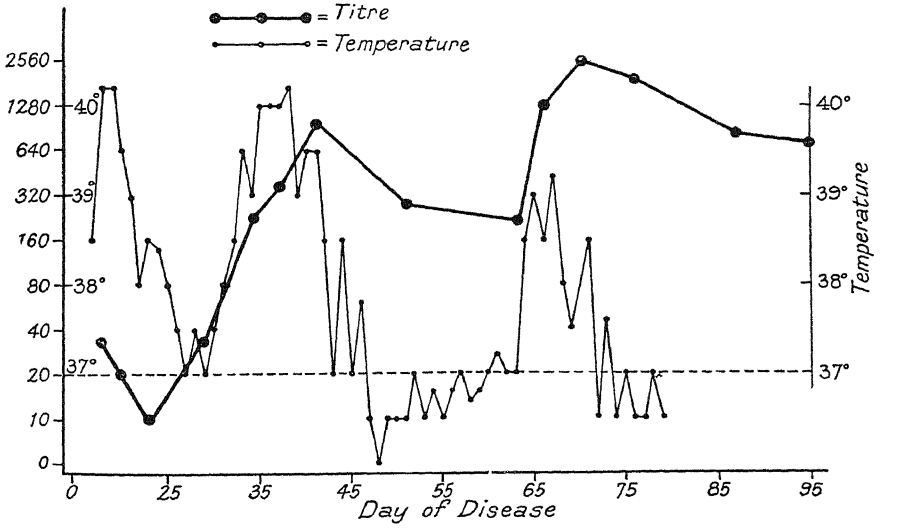

FIG. 261.

Fluctuations of agglutinins in blood of patient during attack of typhoid fever, followed by two relapses.
(After Jörgensen.)

Whether or not this type of non-specific stimulation occurs can be settled only by empirical trial.

In this connection we may note a terminological confusion which has sometimes arisen in the literature. The production, in response to an antigenic stimulus, of an antibody that has been produced in the tissues on some previous occasion, is often referred to as an *anamnestic reaction* (*anamnesis*—recollection). Sometimes this term is used in connection with the type of non-specific stimulus to which we have just referred—the tissues are stimulated to general activity, in which is included the renewed production of a particular antibody that had been formed at some time in the past. Sometimes, perhaps more accurately, it is employed in reference only to those instances in which the particular chemical stimulus concerned formed part of the earlier experience of the antibody-producing cells. In this limited sense it is clearly synonymous with the secondary response, in the sense defined above, and has no reference to the problem with which we are here concerned.

Several observers have recorded a stimulation of antibody production as the result of excessive or repeated bleeding.

Friedberger and Dorner (1905) stated that the withdrawal of considerable amounts of blood, either shortly before an immunizing injection, or within a few days thereafter, had a definitely stimulating effect on the subsequent antibody production. Hektoen and Carlson (1910), in the experiments already referred to, found that bleeding a dog dry during the initial latent stage of active immunization and immediately transfusing it with the blood of a normal dog appeared to increase the production of antibodies. Hahn and Langer (1917) have reported experiments in which they observed a marked increase in agglutinin titre in 4 rabbits as the result of repeated daily bleedings. Trommsdorf (1921) has recorded an increase in agglutinins for the diphtheria bacillus as the result of daily bleedings. Other workers (Klinger 1918, Landau 1918) have however failed to confirm these results. It may be noted that an opposing factor is brought into play when an immunized animal is subjected to massive repeated bleeding. The mere withdrawal of considerable quantities of blood would, of itself, tend to lower the titre of the circulating antibodies if the antibody-forming apparatus did not share in the subsequent activity of the hæmopoietic tissues. That immunized animals may suffer extensive bleedings without any detectable and lasting fall in antibody titre has long been known (Roux and Vaillard 1893).

Monaco (1939) immunized rabbits with a heat-killed typhoid vaccine, and, 4 months after the last injection, exposed them for 30 minutes to low oxygen pressures; seven exposures were made on alternate days. There was after each exposure a transient rise in blood-agglutinins, and compared with control animals, the exposed animals maintained a higher titre of agglutinins both during and after the exposures. Monaco suggests that agglutinins were mobilized in the blood by the stimulus—oxygen lack—which mobilized the erythrocytes. The effect is clearly analogous to that of bleeding.

It may be accepted that bleeding does act as a stimulus to antibody production in the same sense that it acts as a stimulus to the production of the serum proteins in general; that is, there is an active response tending to make good the loss sustained. Whether this particular stimulus suffices to force the titre, transitorily or for longer periods, far above the pre-existing level is more doubtful.

Another procedure that has been stated to supply a non-specific stimulus to the antibody-forming apparatus is the injection of various metallic salts, colloidal solutions or other substances. We may ignore, from our present point of view, those instances in which the effect of such injections is limited to an increase in the bactericidal power of the blood. Such effects will be more conveniently considered in Chapter 52.

Wallum and his collaborators (Walbum and Mørch 1923, Walbum and Berthelsen 1925, Walbum 1925, 1926, Schmidt 1926, Ørskov and Schmidt 1928) have recorded

numerous experiments along these lines. They conclude that the injection of salts of certain metals, especially those of cobalt, manganese and beryllium, causes an increase in the production of antitoxin, or of agglutinins, if given early in the course of immunization, and leads to a secondary rise in titre, if injected when the antibody titre has commenced to fall. Several investigators have, however, failed to confirm these observations (McIntosh and Kingsbury 1924, Horgan 1925), and the protocols included in some of Walbum's reports suggest that the response is very irregular.

Steabben (1925) studied the effect of various colloids on antibody production. Using agar, gelatin, a silver sol and an iron sol, she found that the injection of these colloids had no power to increase the antibody titre when this had become steady, though the injection of such a colloid at the same time as the bacterial antigen might increase the antibody response. This last effect is clearly analogous to the adjuvant action of certain substances on the response to an antigen, already discussed on p. 1115.

Obermayer and Pick (1904) recorded that animals immunized 3 months previously showed a fresh formation of precipitin after the injection of a 5–10 per cent. solution of peptone. Fleckseder (1916) stated that the injection into human beings of deuteroalbumose or nucleic acid gave rise to an increase in the agglutinins for typhoid bacilli which were already present in detectable amount in the subjects in question. Weichardt and Schräder (1919) noted a definite increase in agglutinin titre after the injection of deuteroalbumose, sodium nucleinate or milk. Matsuda (1924) reported that the injection of deuteroalbumose was followed by a secondary increase in the disappearing viricidal antibodies in the blood of vaccinia-immune animals. Wahl (1938) records a similar effect in rabbits immunized against *Salm. typhi* and *V. cholerœ*. Weichardt (1922) and Wahl both review the data with regard to the effect of protein substances as non-specific stimuli; in most cases the stimulus is irregular, and the antibody response is small compared with that to a specific antigenic stimulus.

Finally we may consider those cases in which the non-specific stimulus is provided by a complex antigen, similar in type to that providing the initial specific stimulus but possessing no known common antigenic factor. So far as this antigenic dissimilarity is in fact complete the case does not differ in its essentials from those we have considered above.

Dreyer and Walker (1909) recorded a secondary rise in agglutinins for *Bact. coli*, following the intraperitoneal injection of killed staphylococci into previously immunized rabbits. Conradi and Bieling (1916) state that rabbits immunized against *Salm. typhi* show a secondary rise in agglutinins after various non-specific stimuli, such as those provided by the injection of *Bact. coli*, dysentery bacilli and *C. diphtheriœ*. Tsukahara (1921) records a series of experiments which are highly suggestive. He injected rabbits with typhoid, paratyphoid and dysentery bacilli, using one organism as the primary specific stimulus and another as the secondary non-specific stimulus, and noted many instances of a secondary rise in agglutinins. A careful perusal of his protocols, however, indicates very clearly that, where the secondary response was well marked, there was some antigenic relationship between the two kinds of bacteria employed, indicated by the fact that a primary inoculation with one of them was followed by a slight but definite production of antibodies acting on the other. This fact, of course, excludes these particular examples from the category which we are considering.

Rosher (1924) was unable to detect non-specific stimulation of antibody production in any of the following instances: primary specific antigen *Bact. coli*, secondary non-specific inoculum *Staph. aureus*; primary specific antigen *Bact. coli*, secondary non-specific inoculum sheep's red cells; primary specific antigen *Salm. paratyphi A*, secondary non-specific inoculum suspension of mixed unrelated bacteria; primary specific antigen *Salm. typhi*, secondary non-specific inoculum *Salm. paratyphi B*; primary specific antigen *Salm. enteritidis*, secondary non-specific stimulus infection with living tubercle bacilli.

In all cases in which this point was examined, the secondary inoculum acted as an effective primary specific stimulus, inducing the production to a relatively high titre of antibodies reacting with its own antigenic components, while leaving the titre of antibodies acting on the previously injected antigen unaltered. Analogous results had been noted by many of the observers referred to above.

To summarize, we may say that there is some evidence that non-specific stimuli —extensive bleeding, or the injection of metallic salts or colloids or protein solutions or unrelated bacteria—may induce (*a*) an increase in the titre of a normal antibody, (*b*) an increase in the production of immune antibodies when administered during the early stages of immunization, or (*c*) a secondary rise in titre when administered after the effect of the preliminary specific immunization has reached its maximum, or declined from it. The effects summarized under (*b*) may well be due to adjuvant effects such as we have discussed above. Wahl (1938) indeed attributes them to the induction of an inflammatory lesion which absorbs and retains antigen still present in the body. The responses falling within these categories are, however, irregular, usually trivial, and never comparable to those which follow the reinjection of the specific antigen. It is quite certain also that the injection of a given antigen may stimulate the antibody-forming apparatus to the energetic production of the corresponding antibody, without any detectable production or mobilization of antibodies acting on an unrelated antigen to which it had previously responded.

The Fate of Antibodies when injected into a Normal or Immunized Animal.

This is a convenient place in which to note a series of observations which, while not immediately related to the phenomena that we have been discussing, are of considerable practical importance.

When we inject an antibody-containing serum into a normal animal, the rate at which it reaches the blood stream and the maximum concentration which it there attains are in great part determined by the route of injection. Obviously we shall obtain the most rapid effect by injecting our antiserum intravenously. Injection by any other route will involve a lag period before the maximal concentration is reached in the circulating blood; and since the antibody-containing serum is being slowly eliminated throughout the whole period the concentration in the blood and tissue fluids in general will reach a lower level.

Smith (1907) records a series of experiments that serve to illustrate these points.

Fig. 262 shows the disappearance of agglutinins for *Bact. coli* from the blood of a rabbit after an intravenous injection of the serum of an immunized goat.

Fig. 263 shows the effect of inoculating the same serum subcutaneously. It will be noted that the maximal concentration of agglutinin in the circulating blood is not reached until 53 hours after the injection.

Fig. 264 shows the concentration of antitoxin in the circulating blood of a human subject at varying intervals after the subcutaneous injection of an antitoxic serum. It will be noted that the peak is not reached until the 3rd or 4th day.

The intravenous injection of antiserum is not necessarily followed by an immediate establishment of a maximum antibody level in the blood. In man, Finland and Brown (1938) noted that maximum titres were not reached until 5 and sometimes 10 hours after intravenous injection. This phenomenon is not readily explained, except in terms of a rapid absorption of antibody to the tissues, and a subsequent shift in the blood-tissue antibody equilibrium, during which antibody is released into the blood. The studies of Fink *et al.* (1944) on the metabolism of plasma proteins in the dog provide some support for the explanation, for it appears that the plasma proteins are normally in constant and

Rise and fall of antitoxin in blood of human subject after subcutaneous injection of antitoxic serum.

(After Smith.)

rapid exchange with a readily mobilizable pool of body protein. It is not impossible that injected antibodies may participate in this exchange. In this connection we may note that a large proportion of intravenously injected antibody may disappear from the circulation in a relatively short time. For example, Sédallian, Jourdan and Clavel (1937) replaced the blood of normal rabbits with that from actively immune rabbits, and found that within 10 minutes the antibody titre was one-tenth that to be expected on the basis of dilution of the donor blood in the blood of the recipient animal.

It may be noted that an antiserum injected into the peritoneum rapidly reaches the blood stream *via* the thoracic duct, so that the effect does not differ greatly from that of an intravenous injection. After an intramuscular injection an anti-

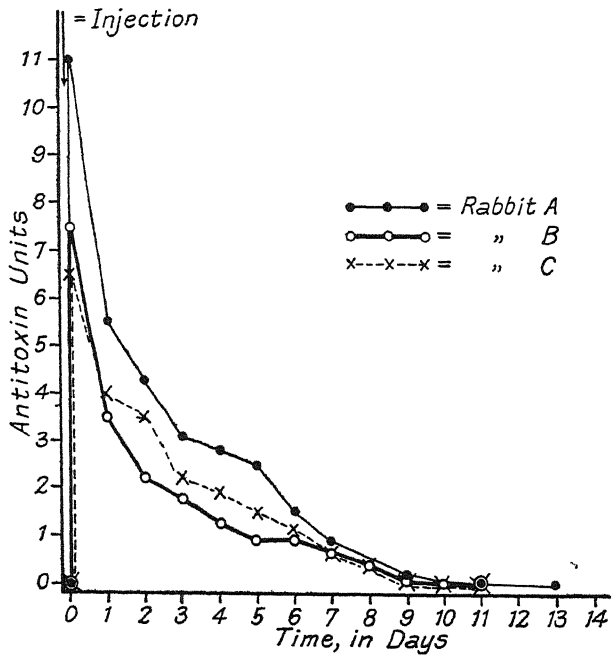

FIG. 265.

Disappearance of antitoxin from blood of three normal rabbits, after intravenous injection of antitoxic horse serum.

(After Glenny and Hopkins.)

Disappearance of antitoxin from blood of three rabbits, previously sensitized to normal horse serum, after intravenous injection of antitoxic horse serum.

(After Glenny and Hopkins.)

serum reaches the blood stream more slowly than after an intraperitoneal injection but more rapidly than after a subcutaneous injection.

Another point of some importance in connection with passive immunization is illustrated in Figs. 265 and 266 (Glenny and Hopkins 1922).

In Fig. 265 is recorded the rate of disappearance of antitoxin from the circulation of 3 normal rabbits after the intravenous injection of 0·5 ml. of diphtheria antitoxin, derived from the horse. Fig. 266 gives a similar record in the case of 3 rabbits that had received previous inoculations of horse serum. These were "immune" or "sensitized" to horse serum—the relation of the immune to the sensitized state is discussed in Chapter 51—and in consequence eliminated the antibody from their circulation much more rapidly than did the normal rabbits.

The same phenomenon will occur when a person who has previously received an injection of horse serum is given an antitoxic or antibacterial serum derived from that animal (see Hooker and Follensby 1931).

The influence of previous sensitization may be even more marked when an antiserum is injected by the subcutaneous or intramuscular route. The cells of a sensitized or immunized animal take up, or fix, some of the antibody distributed throughout the tissues *via* the circulating blood. As a result these cells, or some of them, are able to combine specifically with the corresponding antigen. The intracutaneous, subcutaneous or intramuscular injection of an antiserum prepared in the horse into an animal already sensitized to horse serum, appears to be followed by the fixation of a large proportion of the serum at, or in the neighbourhood of, the site of injection, with a consequent reduction in its therapeutic or prophylactic effect (see Kahn and McDermott 1934, Kahn 1934, Schmid 1938*b*). The fixation is not necessarily due to an absorption of the injected serum to antibody specific for it in the tissues. The inflammatory lesions that follow the injection into the sensitized tissues may also hold the serum in a non-specific manner. Finland and Brown (1938) record that the absorption of antipneumococcal sera was slowest with sera that induced the more severe local reactions upon intramuscular injection.

The Physiological Fate of Antibodies.—The disappearance of passively administered antibody from the circulation within a few weeks suggests that they are rapidly metabolized by the tissues. Normal plasma proteins, including globulins, are utilized by the body as food-stuff (see, for example, Holman *et al.* 1934) and it is reasonable to assume that antibodies are similarly susceptible to tissue enzymes. In this case the antibody levels observed in the blood of actively immunized animals must be maintained by an excess of production over destruction, a destruction which presumably is as rapid as that of passively injected antibodies. Heidelberger, Schoenheimer and their colleagues (Heidelberger *et al.* 1942, Schoenheimer *et al.* 1942) using dietary amino-acids marked with isotopic nitrogen (N_{15}) have shown that the dietary amino-acids are incorporated into the plasma proteins, including the antibodies, of an actively immunized animal, but not into passively injected antibodies. The rate of appearance and disappearance of the marked nitrogen from the blood stream indicated that antibody was formed rapidly from the dietary amino-acids, and had a " half-life " of about 2 weeks, a finding which accords well with the inferences drawn from the data for the disappearance of passively administered antibody.

The Mechanism of Antibody Formation.

As to how antibodies are formed, with the single exception of Pauling and Campbell's (1942) work, we have no positive knowledge that is based on direct experiment. In the early days of immunology the hypothesis that the injected antigen was in some way incorporated in the antibody was tentatively advanced. It had the obvious merit of offering a possible explanation of specificity, but was soon abandoned because of the enormous quantitative disparity between the antigen injected and the antibody formed. More recently it has been revived in a less direct form ; but it is difficult to accept in any form at all.

In certain of the experiments recorded above it was calculated that the dose of active antigenic material injected into a 2,000 gm. rabbit was of the order of 0·000,000,5–0·000,005 mgm., yet this dose might result in the production of agglutinin to a titre of 1 : 500. Hooker and Boyd (1931) have calculated that, taking such relationships into account, one molecule of active antigenic substance must give rise to an amount of antibody globulin sufficient to agglutinate 600 bacteria ; and, since the surface relationship between one molecule of globulin and 600 bacteria is of the order of 1 : 25,000,000, there seems no room for any hypothesis which assumes the permanent incorporation of any fraction of the antigen in the antibody complex. Berger and Erlenmeyer (1931) and Hooker and Boyd (1931, 1932) have examined

this question experimentally, using a linked synthetic antigen containing arsenic, and testing for the presence of arsenic in the antibody-containing serum. These tests were entirely negative and the limits thus set to the amount of antigen present in the antiserum appear to render it impossible that a molecule of antibody can contain any grouping derived from the antigen. If the antigen is incorporated in the antibody at any stage in the formation of the latter, it must apparently be released again, perhaps leaving its impress on the complex of which it once formed a part, and by repeated reassimilation modifying successive fractions of the serum globulin (see Topley 1930).

A working hypothesis of the method of antibody formation, that has a reasonable *a priori* probability and accords well with our present knowledge of the structure of antigens and antibodies, has been put forward independently by Breinl and Haurowitz (1930), Alexander (1931) and Mudd (1932). Ignoring minor differences in the views of its sponsors, this hypothesis assumes that all antibodies are globulins newly synthesized under the directing influence of the antigen. This influence is exerted through a union, physical or chemical, between the peptides or amino-acids and the active groupings of the antigen, during the globulin synthesis. Mudd lays special stress on the point that this synthesis occurs at the interface between the antigen and the surrounding fluid, a point of particular interest in view of the observation that the antibody content of an antibacterial serum seems to be largely determined by the nature of the active groupings at the cell surface. The globulin thus formed is assumed to be dissociated from the antigen after a certain stage has been reached, and the latter is thus able to leave its stereochemical imprint on successive molecules of antibody globulin, synthesized under the same conditions. Breinl and Haurowitz would locate this synthesis in the reticulo-endothelial cells, the antibody globulin being released when these cells disrupt; or, as Sabin (1939) has suggested, both normal and antibody globulin may be shed into the blood stream from the outer layer of the reticulo-endothelial cell. Pauling (1940) has reviewed the physico-chemical bases of the hypothesis, and considers that the difference between normal and antibody globulin lies not in the ordering of the amino-acid residues of the polypeptide chains, but in the manner of the folding of their otherwise similar constituent polypeptide chains, to form polypeptide laminæ and ultimately the globular protein. According to Pauling, the ends of the folds, which when packed together will constitute one of the surfaces of the completed molecule, are capable of taking up many configurations, whose variety and stability are determined by the presence of an excess of proline and hydroxyproline residues at the point of folding. When an antigenic substance with a well-defined configuration of active groups is present in the cell, it influences the configuration at the ends of the folded polypeptide chains, thereby inducing the formation of an antibody receptor. Pauling suggested that if globulin molecules were unfolded by denaturing agents and allowed to re-fold in the presence of an antigen or hapten, antibody might be formed.

Pauling and Campbell (1942) reported the *in vitro* synthesis of antibody-like protein by this means, thus providing strong support for their hypothesis. When ox γ-globulin was partly denatured by exposure to 57° C. for 14 days, in the presence of the azo-dye dihydroxy-tri (*p*-azophenylarsonic acid) benzene, a precipitate of dye and protein was formed, presumably consisting of modified globulin united specifically to the " antigen." The dye was then displaced from the insoluble complex by dialysis against a solution of its " determinant " group, namely sodium *p*-amino-phenylarsonate, and the arsonate then removed by dialysis against NaCl. About 15 per cent. of the protein in the resulting solution had certain antibody properties; it was specifically precipitated by the azo-dye,

and precipitation was specifically inhibited by the arsonate. A similar specific modification of ox-globulin was produced, using the polysaccharide of the Type III pneumococcus as the "antigen."

Burnet (1941) has pointed out a number of features of antibody-formation that do not accord well with the "scaffold" hypothesis. In the first place the hypothesis demands the presence of antigen in the tissues as long as active immunity lasts. Immunity to smallpox, for example, may last 20 years (see Chapter 86). Are we, therefore, to conclude that the smallpox antigens remain in the tissues for 20 years? We can clearly postulate a persistence or a slow multiplication of virus in the body over this period, or the maintenance of immunity by continued reinfection (see Chapter 55). At present, however, the evidence for this view is purely question-begging, in that it is based on observations of long-lasting immunity. As regards the persistence of inanimate antigen, we have little relevant information. Antigenic material like bacteria and red cells rapidly disappears from the reticulo-endothelial cells, but we have no basis for supposing that their constituent parts disappear with equal rapidity, and it is not necessarily absurd to assume that long-lasting immunity is equivalent to a long-persisting antigen. But even so, we shall have to decide where it persists. Returning to our smallpox example, it is reasonable to suppose that in 20 years the reticulo-endothelial cells of the tissues will be the remote descendants of those that originally ingested the antigen, in which case the persisting antigenic units must pass to one of the daughter cells at each division. Burnet prefers the assumption of an antibody-forming capacity, independent of the continued presence of antigen, which is transmitted to descendant cells by some hereditary process.

He postulates that the serum globulins are products of self-reproducing, intracellular, globulin proteinases, and represent a stage in synthesis when the molecule has the essential structure of the enzyme, but is without enzymic activity. At this stage it may be turned out into the circulation as a globulin. In the cell, however, the synthesis proceeds to completion, and more proteinase is formed. In the presence of antigen, the configuration of the proteinase is modified so as to hydrolyse the antigenic matter, and, when the antigen is gone, the proteinase reproduces itself in the modified form, both in the original cell and its descendants. According to Burnet, the continuously accelerated output of antibody observed during the secondary response is characteristic of an autocatalytic process such as he postulates, not the production of antibody from a fixed number of antigenic scaffolds; and he attributes the change in reactivity of antibody observed with prolonged immunization (see Chapter 7) to the profounder modification of the globulin proteinases by the products of a more complete intracellular hydrolysis of the antigen.

We are not in a position to decide between these hypotheses. Both depend upon arguments by analogy with other biological processes, and it is not in all cases clear how relevant these analogies are. The student is referred to Pauling (1940) and Burnet (1941) for a fuller discussion. The evidence is also reviewed by Sevag (1945), who develops the conception of antigens as specific catalysts of antibody formation, basing his argument on a number of analogies between the properties of antigens and enzymes. This, it may be noted, is in direct contrast to the views of Burnet, who regards antigens as modifiers of the intracellular proteinases.

SUMMARY

(1) The available evidence indicates that the cells of the reticulo-endothelial system, which are known to remove injected antigenic material from the blood and tissue fluids, play an essential part in the production of antibodies. Whether these cells themselves produce the antibodies in their final and complete form, or whether their rôle is confined to the temporary retention of antigen and its subsequent liberation in an altered or unaltered state, the actual synthesis of antibodies occurring elsewhere, cannot yet be determined. The present indications are that the part played by the reticulo-endothelial system is not confined to the retention and release of unaltered antigens. There is also evidence that lymphoid tissue is concerned in the production of antibodies.

(2) The antibody-forming apparatus responds in a characteristic way to a specific stimulus provided by the introduction of an antigen into the tissues. This response differs as regards its time relations, extent and even its occurrence or non-occurrence, in different animals and with different antigens, but its general form is of a well-defined type. Following an optimal injection of an antigen which evokes an effective primary response there is a lag period of a few days followed by the appearance in the blood of the corresponding antibody. The titre of this antibody rises rapidly to a maximum which is usually attained between the 10th and 22nd day after inoculation. It then falls, at first rapidly then more slowly, reaching a level which is maintained with little alteration for several months. The final disappearance of antibodies from the blood stream may not occur for many months, or even years.

(3) The amount of antibody produced in response to a single injection of antigen varies with the amount of antigen injected. There is a threshold dose—often extremely small—below which no response is obtained. With increasing doses there is an increase in antibody production as judged by the maximal titre attained in the blood, but the increase is not in simple proportion; a large increase in dosage usually results in a relatively smaller increase in titre. As the dose increases still further the ratio of increase in titre to increase in dose grows smaller and smaller, until a maximum effective dose appears to be attained, provided that a lower limit of dosage is not imposed by the toxicity of the antigenic material.

(4) The antibody-forming apparatus is capable of responding simultaneously to the injection of several different antigens, but with more than two or three antigens the multiple response tends to be less effective against any one antigen than if it were responding to that antigen alone.

(5) The antibody-forming apparatus displays a characteristic difference in its response to primary and subsequent injections of the same antigen. Following a secondary stimulus antibody production is usually more rapid and more copious than after the primary stimulus, and the decline in titre of circulating antibodies after a maximum has been reached is usually delayed. An immunized differs from a normal animal, not only in the possession of a particular antibody, but in its capacity to produce that antibody rapidly and in large amount in response to the specific stimulus.

(6) Repeated inoculations are on this account more effective in raising the antibody titre to a high level than a single injection, even of a very large dose. Just as there appears to be a limit to the titre that can be attained by increasing

the size of a single dose of antigenic material so there is a limit beyond which repeated injections fail to force the titre.

(7) The injection of a large dose of antigen into an animal in whose blood the corresponding antibody is present frequently results in a temporary fall in the concentration of that antibody, followed in most cases by a secondary rise.

(8) Antibody formation may be induced by the administration of antigens by the mouth, by inhalation, or by intranasal instillation. Administration by these routes is, in general, less effective than direct inoculation into the tissues. In the case of administration *per os* there is evidence that antibodies may be produced against certain antigenic components but not against others.

(9) Although the majority of naturally occurring antigens are proteins, or contain protein components, recent observations have shown that other substances, such as complex polysaccharides, are capable of inducing an active immunity, and of stimulating antibody production.

(10) The antibody-producing apparatus may in certain conditions be stimulated by non-specific substances. Two effects may be distinguished:

(*a*) An adjuvant action of substances injected into the tissues simultaneously with antigen, or during the period of increasing antibody response. Adjuvants appear to act mainly by inducing tissue lesions from which the absorption of antigen, and its consequent elimination, is retarded. A stimulus to the multiplication of antibody-forming cells cannot be excluded from the adjuvant effect.

(*b*) A stimulation of the antibody-forming apparatus that results in some increase in the concentration of a normal antibody or in the renewed production or mobilization of an antibody previously produced in response to a specific stimulus. The evidence for such stimulation is conflicting; it is clear that this non-specific response occurs very irregularly, is usually trivial or transitory in its effect, and is never comparable to the response to a further injection of the specific antigen.

(11) The rate at which antibody, contained in any foreign antiserum, reaches the blood and tissue fluids of a normal animal and the concentration there attained depend in great part on the route by which the antiserum is injected. If the animal or man has received a previous injection of any serum of the same animal origin the antibody will be eliminated at a greatly increased rate.

(12) The mechanism of antibody formation still awaits elucidation. Various hypotheses have been advanced, but none of them completely covers the observed phenomena. The most generally accepted working hypothesis—that the configuration of the globulins is modified during synthesis in the presence of antigen so that the surface of the completed molecule is complementary to the antigenic surface—has the support of a recent demonstration of the *in vitro* modification of globulins in the presence of antigens, with the production of proteins having some of the properties of antibody produced *in vivo*.

CHAPTER 51

ANAPHYLAXIS, HYPERSENSITIVENESS AND ALLERGY

In the preceding chapters we have considered a series of reactions most of which have as a common factor the property of affording specific protection against bacteria or their products. Numerous observations, both clinical and experimental, have afforded instances of the contrary condition, in which an individual is, or may be rendered, more susceptible to some noxious agent than are the generality of his own species. In some cases an individual may become highly sensitive to an agent which is entirely innocuous to his normal fellows. The phenomenon of hypersensitiveness is presented in its clearest and least ambiguous form when the exciting agent is some non-living material, so that there is no question of multiplication within the body or of the complex and variable tissue reactions that are associated with bacterial infection. It will be convenient to consider first the data relating to this type of abnormal sensitivity, and then to discuss its bearing on the phenomena of bacterial disease. It will also simplify matters to start with the most striking and clear-cut case of hypersensitiveness—the phenomenon of acute anaphylactic shock.

ANAPHYLACTIC SHOCK

The detailed study of this curious reaction dates from the beginning of the present century, though several observations are on record in the earlier literature which with our fuller knowledge we can recognize as undoubted examples of anaphylaxis. The observations of Richet and his co-workers (Portier and Richet 1902, Richet 1907) first drew general attention to the experimental facts; though the issue was at this stage obscured by the chance that the agent selected for study was itself toxic for the experimental animal employed. Richet observed that dogs which had survived a single injection of an extract of certain actinians might succumb rapidly, and with a curious and characteristic symptom complex, to a second injection of the same material given after days or weeks. It was this substitution of increased susceptibility for the increased resistance which usually follows the injection of sublethal doses of a toxic material that led him to coin the term *anaphylaxis*.

At about the same time Theobald Smith in America had noted the abnormal sensitiveness of guinea-pigs to widely spaced injections of toxin-antitoxin mixtures. He communicated these observations to Ehrlich in 1904; and Otto in 1905 published the results obtained in a detailed study of this phenomenon. He showed that the horse serum in the mixtures, not the toxin, was the essential agent; that an interval of 10 days elapsed after the sensitizing dose before hypersensitiveness

was established; and that no hypersensitiveness resulted when large injections of serum were given at short intervals.

The same phenomenon was studied independently by Rosenau and Anderson (1906, 1907), who established the strict specificity of the reaction. They found that guinea-pigs sensitized to horse serum showed little if any hypersensitiveness to the serum of other animals, such as the rabbit, cat, dog, pig, sheep, chicken or man. Similarly, guinea-pigs sensitized to horse serum did not respond in any abnormal way to the subsequent injection of egg-white, vegetable protein or milk. They noted also that the amount of serum required to produce sensitization was extremely small; as little as 0·000,001 ml. sometimes induced typical hypersensitiveness. The amount required to produce anaphylactic shock in a sensitized animal was, however, considerably greater (0·01–0·1 ml.). They confirmed the existence of a latent period of 10–12 days between the sensitizing injection and the establishment of the anaphylactic state, and noted that, once established, this state lasted for an indefinite period, extending over several months at least.

These observations have been repeatedly and consistently confirmed by later workers. Animals may be actively sensitized by the injection of any substance that is antigenic in the full sense. The sensitizing injection may be given by any route. Often a single sensitizing dose suffices. In some animals, and with some antigens, it is necessary to give more than one sensitizing injection, and to use doses far larger than the minute amount that suffices in the particular case of the sensitization of the guinea-pig to horse serum; but the same principle holds—the injections must not be too large, nor too often repeated.

As regards the shock-inducing, or "shocking" injection, either the antigen used for sensitization, or certain types of separated haptens containing the specific reactive grouping, are effective in eliciting the characteristic symptoms. The route of injection is important. Intravenous inoculation gives the most constant results; in some animals it is the only effective route for this purpose. In the guinea-pig, which is peculiarly susceptible in this respect, shock may be produced by intraperitoneal inoculation, but larger doses are required. Within certain limits the size of the shocking dose, nevertheless, appears to be a secondary factor in determining the severity of shock. In dogs, for example, Dragstedt (1943*b*) found that shock did not become more fatal with increase in size of the shocking doses; the fatality was primarily determined by the degree to which the animal had reacted to the sensitizing dose.

A curious and significant fact emerged early in the widespread investigation which followed the opening-up of this new field of research. The symptoms and lesions of anaphylactic shock were found to be constant for a given animal species, irrespective of the nature of the sensitizing antigen; while these symptoms and lesions differed sharply from one animal species to another. Thus the guinea-pig reacts in the same way when anaphylactic shock is produced with horse serum, egg albumin, milk or various bacterial antigens; but the reactions of the sensitized guinea-pig, rabbit and dog to horse serum differ sharply and characteristically from one another.

Anaphylactic Shock in the Guinea-pig.—After a sensitized guinea-pig has received an intravenous injection of the specific antigen, it at first remains quiet; but within a minute marked restlessness develops. The hair begins to bristle over the head and neck, and the animal usually rises on its hind legs, rubs its nose vigorously, and emits loud spasmodic sneezes. Often it gives a jump, or a series of jumps. Within a few minutes tonic and clonic convulsions set in, and the animal falls on its side. The respiration

becomes slow, the mouth opening with each violent inspiratory effort; and breathing ceases within a few minutes. The heart continues to beat for several minutes after breathing has ceased.

The post-mortem findings were first described in any detail by Gay and Southard (1908); but it is to Auer and Lewis (1910) that we owe the first adequate account of the physiological reactions that lead up to the fatal issue. In guinea-pigs examined immediately after death from fatal anaphylactic shock, these observers confirmed the presence of intestinal congestion and the occurrence of active peristaltic movements that had been previously noted. They observed the frequency of hæmorrhages on the under side of the diaphragm, and noted, as Gay and Southard had done, the distension of the lungs; but they showed that this distension was not due to simple emphysema. The lungs remained distended long after the thorax was freely opened. Even when removed from the body they showed no sign of collapse; and portions cut off from the pulmonary lobes, if not too small, remained in their condition of dilatation. More detailed examination showed that the distension was caused by contraction of the bronchioles, which retained the inspired air in the dilated alveoli. The death of the animal was clearly referable to suffocation consequent on this obstruction to respiration. Auer and Lewis showed that the bronchiolar contraction was not prevented by section of the vagi or by the administration of curare, and was therefore of muscular or immediately neuro-muscular origin. They showed also that the blood pressure during anaphylactic shock at first rose considerably and then fell slowly but steadily till death, as one would expect in asphyxia.

By varying the mode of administration of the shocking dose, a delayed fatal shock may be produced in guinea-pigs, in which the pulmonary emphysema is absent, and the gross changes in the organs are confined mainly to intestinal congestion and hæmorrhage (Williamson 1936).

Anaphylactic Shock in the Rabbit.—The rabbit, like the guinea-pig, suffers from acute anaphylactic shock if the sensitization is adequate, and if a sufficient amount of antigen is subsequently administered by the intravenous route. The reaction is not, however, so readily elicited. The symptoms of shock differ in several important respects. The preliminary signs of irritation, the coughing and the violent inspiratory efforts are absent. The animal lies with outstretched legs or falls on its side, gives a series of convulsive movements often associated with the passage of urine and fæces, and dies. In many cases irregular respiratory movements continue for a brief period after the heart has ceased to beat—a reversal of the order of cessation observed in the guinea-pig. At necropsy the pulmonary dilatation, which is so striking a feature in the guinea-pig, is absent in the rabbit. The most characteristic abnormality found in the latter is the extreme dilatation of the right side of the heart. Coca (1919) showed that this dilatation was associated with marked obstruction to the pulmonary circulation, evidenced by the increased pressure required to drive fluid from the pulmonary artery to the left auricle. He concluded that acute anaphylactic death in the rabbit was due to a spasmodic constriction of the branches of the pulmonary artery, followed by rapid dilatation of the right side of the heart and acute heart failure. His observations and conclusions have been confirmed by other workers (Drinker and Bronfenbrenner 1924, Grove 1932*a*, *b*).

Anaphylactic Shock in the Dog.—A sensitized dog, after receiving an intravenous injection of the specific antigen, shows marked signs of restlessness and excitement. Within a few minutes the animal vomits and usually passes urine and fæces, the latter sometimes blood-stained. It then collapses and lies prone. The muscles of the limbs are relaxed. and the dog appears extremely weak. Respiration is slow, and often deep and laboured, Stridor may be heard, and a little froth may exude from the lips. In rapidly fatal shock the weakness progresses, renewed diarrhœa and vomiting set in, and coma, occasionally associated with epileptiform convulsions, leads on to death. It has been pointed out by Dean and Webb (1924) that the reaction almost always occurs in two stages, the initial acute symptoms being followed by some signs of recovery. In fatal cases these soon give

place to the second stage of increasing collapse. In other instances severe initial shock is followed by a rapid return to normal.

As pointed out by Biedl and Kraus (1909), anaphylactic shock in the dog is associated with a progressive fall in blood pressure; later investigations (Pearce and Eisenbrey 1910, Dale 1920*b*) have made it clear that this is not due to any failure of output from the heart or to any influence of the central nervous system, but to the collection and stagnation of the blood somewhere in the tissues. The studies of Dale and his colleagues (Dale 1920*b*) render it highly probable that capillary dilatation is the essential factor.

Manwaring (1910) performed a large number of experiments in an attempt to localize the site of reaction; and, having found that shock did not occur when the abdominal vessels were ligated, proceeded to explore the rôle of the various abdominal viscera by a series of operative experiments designed to exclude each in turn. He found that the exclusion of the liver inhibited acute shock in dogs; and his observations have been amply confirmed by subsequent workers (Voegtlin and Bernheim 1911, Denecke 1914). These results accord well with the findings at necropsy. The congestion of the abdominal viscera has been noted by many observers; and Weil (1917) points out that in dogs dying of anaphylactic shock in its acutest form the single outstanding feature at necropsy is the enormous distension and congestion of the liver.

We may briefly note certain additional phenomena, which seem to be general to anaphylactic shock as displayed by any of the species so far investigated, though not developed to an equal degree in all of them. There is commonly a marked leucopenia; and this, as Webb (1924) has shown, is associated with an aggregation of polymorphonuclear cells in the capillaries of the lungs, a phenomenon clearly analogous to that which follows the intravenous injection of bacteria in immunized animals. In rabbits, the arterioles of the ear are conspicuously contracted during shock; circulating leucocytes adhere to the capillary walls and in some cases form leucocytic emboli (Abell and Schenk 1938). Removal of circulating leucocytes and their retention in the tissues has also been demonstrated by Dragstedt, Ramirez de Arellano and Lawton (1940) in the isolated lung of sensitized rabbits, when perfused with blood containing the specific antigen. There is a decrease in the coagulability of the blood, most marked in the dog. The work of a number of investigators (see Dragstedt 1941) has excluded changes in the blood elements concerned in normal coagulation as the cause of this phenomenon, which appears to be due to the liberation of heparin during shock (Jaques and Waters 1940). There appears to be a decrease in the amount of complement in the circulating blood; and there is a marked fall in body temperature.

Anaphylactic Shock in Other Animals.—Although the guinea-pig, rabbit and dog have been studied more extensively than any other species in regard to their anaphylactic reactions, a considerable number of experiments have been carried out on other animals; and it is instructive to note that, in addition to striking differences in behaviour and physiological reaction during anaphylactic shock, various species differ widely from one another in the ease with which they can be sensitized. Thus, among rodents, the rat appears to occupy a peculiar position in that it is extremely refractory to sensitization (Longcope 1922, Parker and Parker 1924, Spain and Grove 1925); though an anaphylactic response can be demonstrated under suitable conditions (Kellaway 1930). Mice are also resistant, though Weiser and his colleagues (1941) point out that the refractoriness varies with the breed of animal, and in some cases depends on insusceptibility to sensitization, not to insusceptibility to shock. In both the rat and the mouse adrenalectomy increases the susceptibility to shock. Birds, so far as they have been examined, may be sensitized by the usual procedures (Friedberger and Hartoch 1909); and the anaphylactic reaction in the pigeon has been studied in some detail (Gahringer 1926, Hanzlik and Stockton 1927). Sensitization to foreign proteins, associated with phenomena which are anaphylactic in kind but do not include typical shock, has been described in cold-blooded animals such as the frog (Goodner 1926). In monkeys, and this is of particular interest for the student of human pathology, sensitization appears to be induced irregularly and with considerable

difficulty. Zinsser (1920) reports his failure to sensitize *rhesus* or ringtail monkeys with a single injection of horse serum; and he could produce only mild anaphylactic symptoms after treatment with repeated doses of antigen. Shock is accompanied by a diminution in circulating platelets, and, as in other animals, a profound leucopenia (Kinsell *et al.* 1941).

The problem of human anaphylaxis will be most conveniently considered in relation to the problem of natural hypersensitiveness.

Passive Anaphylaxis.

It was noted by some of the earliest workers in this field that female guinea-pigs which had been actively sensitized gave birth to young that were themselves hypersensitive. Otto (1907) first demonstrated that the anaphylactic state could be passively transferred by injecting the serum from an anaphylactic into a normal animal, and in so doing placed anaphylactic shock in the category of the *in vivo* antigen-antibody reactions. His findings were soon confirmed and extended by other workers, in particular by Doerr and Russ (1909), and the numerous observations which have since been recorded place the following propositions on a firm basis of experimental fact, so far at least as the guinea-pig is concerned. A normal animal that has received an injection of the serum of an actively sensitized animal will respond to the subsequent injection of the corresponding antigen by developing acute anaphylactic shock. Passive sensitization may be effected with equal or even greater certainty by an injection of the serum of an animal that has been "immunized" against a given antigen by repeated injections, so that it is not itself sensitive to the antigen in question. In either case the injection of the serum is not usually followed by the *immediate* sensitization of the recipient. An interval of some hours must elapse between the injection of the sensitizing serum and the injection of the corresponding antigen if typical shock is to be regularly obtained. For maximal sensitization the interval is even longer—4 to 6 days (Kellaway and Cowell 1922).

Under suitable experimental conditions, an analogous reaction, "reversed passive anaphylaxis," may be induced in the guinea-pig by injecting antigen first and antibody later (see Kellett 1935). Both in "reversed" and direct anaphylaxis, shock is sometimes produced when the two intravenous injections follow one another immediately (Dean *et al.* 1936, Zinsser and Enders 1936).

The efficacy of an antiserum in the induction of passive anaphylaxis appears to be closely related to its content in specific antibody as recorded by precipitin tests (Doerr and Russ 1909), and there seems no reason for supposing that the reagents involved differ from those with which our other immunological studies have made us familiar. The experimental study of this phenomenon has, however, brought to light a relationship that is probably of fundamental importance in immunological mechanisms. Different antisera, produced by the immunization, or sensitization, of animals of different species against a single antigen, differ widely in their ability to induce passive sensitization in a given species of animal.

Thus, Avery and Tillett (1929) and Brown (1934*b*) found that guinea-pigs could be sensitized to pneumococcal polysaccharides by the injection of antipneumococcal sera prepared in the rabbit, but not by antipneumococcal sera prepared in the horse. Again (see Friedberger and Hartoch 1909, Scott 1931, Hartley 1940), guinea-pigs cannot be sensitized with the serum of fowls, oxen, goats, sheep, and pigs, and pigeons cannot be sensitized with the serum of rabbits. The mouse would appear to resemble the guinea-

pig, in that it can be passively sensitized with antipneumococcal serum prepared in the rabbit but not with antipneumococcal horse sera (Mehlman and Seegal 1934). Chicken antisera will not sensitize mice (Weiser *et al.* 1941).

The insusceptibility of guinea-pigs to sensitization with equine antibody has been questioned by Bailey, Raffel and Dingle (1937), who reported sensitization by equine antipneumococcal sera, and attributed their success to the injection of large shocking doses of antigen, sufficient to overcome any protection afforded by unfixed antibody (see below) in the circulation. Using equine antisera to hæmocyanin and ovalbumin, Follensby and Hooker (1944) were unable to sensitize guinea-pigs, though the shocking doses of antigen, as in Bailey's experiments, were large, and greatly in excess of the amounts serologically equivalent to the antibody injected (Chapter 7). They suggest that optimal quantitative relations between the antibody and antigen employed cannot wholly explain Bailey's results.

It will be seen in later sections of this chapter that there are reasons for believing that the fixation of the injected antibody by the tissue cells of the recipient is an essential factor in passive anaphylaxis; and it is not surprising to find that the serum globulins of different species behave differently in a reaction of this kind.

The amount of antibody required for passive sensitization has been measured by Kabat and Landow (1942) and Kabat and Boldt (1944). Full sensitization to fatal shock was produced by the injection into guinea-pigs weighing 250 gm., of about 0·03 mgm. of antibody nitrogen; that is, less than 0·2 mgm. of antibody globulin. With this minimal sensitizing dose, the optimal shocking dose of antigen—ovalbumin—was about 50 times the amount reacting optimally in a constant-antibody precipitin titration.

The phenomena of active and passive anaphylaxis appear, as we have seen, to depend on specific reactions of the antigen-antibody type, and there seems no purpose in burdening our vocabulary with additional labels, such as "anaphylactogens" or "anaphylactic antibodies." It is, however, of interest to inquire how partial antigens, or haptens, behave in this reaction.

The Rôle of Haptens in Anaphylaxis.—Tomcsik and Kurotchkin (1928) immunized rabbits against *Bact. aerogenes*, the pneumobacillus, and a yeast. In each case they were able to obtain a high-titre precipitating serum for the polysaccharide hapten extracted from the corresponding organism. Guinea-pigs injected with these rabbit antisera developed acute anaphylactic shock when subsequently injected with the corresponding hapten. Lancefield (1928) sensitized guinea-pigs with the sera of rabbits immunized against hæmolytic streptococci, and induced acute shock by the injection of the separated haptens. Enders (1929) obtained similar results with a polysaccharide fraction from the tubercle bacillus. Avery and Tillett (1929) and Brown (1934*a*) have studied the anaphylactic action of the pneumococcal polysaccharides. These haptens will not induce active sensitization in the guinea-pig, but they will induce acute anaphylactic shock in animals passively sensitized by the injection of precipitating antisera prepared in the rabbit, and these reactions are type-specific. Morgan (1932) records a similar relationship between the specific polysaccharide of *Sh. shigæ* and guinea-pigs passively immunized with the homologous antibacterial serum.

Tillett, Avery and Goebel (1929) have tested the anaphylactic response to synthetic sugar-proteins. They prepared *p*-aminophenol glucoside and *p*-aminophenol galactoside and linked these to serum globulin and to egg albumin. Preliminary precipitation tests showed that antisera produced in rabbits reacted specifically *in vitro* with the carbohydrate groupings. Guinea-pigs passively sensitized by the injection of an anti-glucoside-globulin serum developed typical anaphylactic shock when subsequently injected with glucoside-albumin. Guinea-pigs sensitized with anti-galactoside-globulin serum reacted similarly

when injected with galactoside-albumin. In each case the reaction was shown to be specific. Active sensitization with the globulin compounds, followed after 11 days by injection of the corresponding albumin compounds gave similar results. The unconjugated glucoside or galactoside did not induce shock when injected into sensitized animals, but each inhibited anaphylactic shock when injected immediately prior to the injection of the corresponding carbohydrate-protein compound. Klopstock and Selter (1929) carried out similar experiments and obtained similar results, using compounds of protein with atoxyl, or with the sodium salt of metanilic acid. Landsteiner and Levine (1930) sensitized guinea-pigs to the *d*- and *l*-isomers of *p*-amino-tartranilic acid, in each case coupled to horse globulin. The subsequent injection of the corresponding active groupings coupled to chicken globulin induced anaphylactic shock. The shock could be specifically inhibited by a preliminary injection of a compound of resorcinol with the active grouping concerned. Similar results were obtained with guinea-pigs passively sensitized to *p*-amino-arsanilic acid, the active substance being coupled to tyrosine for the inhibition tests. In later experiments Landsteiner and van der Scheer (1932, 1933, 1938) were able to induce shock by injection of the azo-dye compounds alone into animals sensitized with the appropriate azo-dye-proteins.

Specific Desensitization.—The specific desensitization of sensitized animals was recorded by many of the earlier investigators (Otto 1905, Rosenau and Anderson 1906, 1907, 1908, Besredka and Steinhardt 1907, Gay and Southard 1908). Desensitization—as then observed, and in the sense in which this term is now commonly employed—differs from the inhibitory effect induced by simple haptens in that the desensitizing agent is the complete antigen, which is capable, when administered intravenously in adequate doses, of inducing typical shock. The desensitizing effect is obtained, in place of acute shock, if a very minute dose of antigen is given and repeated, or if rather larger doses are given by a route, such as the subcutaneous, which ensures slow absorption. The essential conditions for success appear to be the administration of an amount of antigen that is adequate in total by some method that prevents any rapid accumulation in the circulating blood. It would seem that desensitization, however it is induced, is purely temporary, the anaphylactic, or hypersensitive state being re-established in a few days or weeks (Valléry-Radot *et al.* 1936, Adelsberger 1936, Gernez 1936).

The Mechanism of Anaphylactic Shock.

It is clear that acute anaphylactic shock, as induced by any of the procedures that have been described above, belongs to the category of the specific antigen-antibody reactions. The only question at issue is the mechanism by which this primary reaction gives rise to the series of events that characterize acute shock in any given animal species.

Two opposing views have been put forward. According to one the reaction between antigen and antibody, occurring in the circulating blood or in the tissue fluids, gives rise to a toxic product, anaphylatoxin, which, acting on susceptible cells, gives rise to the characteristic syndrome. According to the other the primary reaction occurs not in the blood or tissue fluids but on or in the tissue cells; and the reactions that characterize acute shock are due not to any toxicity of the antigen-antibody compound itself, or of any derivative from it, but to cellular disturbances initiated by the antigen-antibody reaction. As we shall see, the picture that has been pieced together during the last few years derives, in all its essential outlines, from the cellular school, though it contains details reminiscent of the anaphylatoxin hypothesis.

The Humoral or Anaphylatoxin Hypothesis.—The chief protagonist of this conception of the mechanism of acute anaphylactic shock was Friedberger (1910, 1912, 1913), who had at an earlier period been one of the sponsors of the cellular hypothesis. Certain difficulties in the latter theory, not easily explicable in the light of the knowledge then available, had caused him to modify his views; but his complete *volte-face* was largely determined by the observation of Friedemann (1909) that a guinea-pig could be poisoned with the characteristic symptoms of acute shock by injecting a mixture of an antigen and its homologous antibody after a brief period of incubation *in vitro*.

The humoral theory in its original form postulated a union of antigen with antibody in the circulating blood, followed by a cleavage of the resulting complex, presumably of the hydrolytic type, and the setting free of toxic degradation products—a conception which seemed to accord well with the findings of Vaughan and Wheeler (1907) on the toxicity of the intermediate products of proteolytic degradation in general. Friedemann's observations, which have been repeatedly confirmed, seemed at first to afford a direct demonstration of the production of anaphylatoxin from antigen and antibody *in vitro*; but it soon became clear that sera could be rendered toxic, in this sense, by a variety of procedures in which antigen and antibody played no part. Thus anaphylatoxin can be produced by incubating normal serum with kaolin (Ritz and Sachs 1911, Keysser and Wassermann 1911, Mutermilch 1913), barium sulphate (Mutermilch), talc (Mutermilch), starch (Ritz and Sachs 1918), inulin (Nathan 1914), or agar (Bordet and Zuntz 1914.)

The humoral theory in its earlier form was often described in terms of Ehrlich's hypothesis—the linkage of complement to antigen by an intermediary amboceptor followed by a proteolysis in which complement acted as an enzyme—and a certain air of probability was lent to this view by the observation that the free complement in the circulating blood may be greatly diminished during anaphylactic shock. But there is no evidence that complement can play such an enzymic rôle; and the *in vitro* toxification of serum by non-specific adsorbents is clearly not explicable in such terms as these. As an alternative hypothesis it was suggested that the formation of an antigen-antibody compound, or the addition to serum of kaolin, starch or similar reagents, might remove some stabilizing constituent, perhaps antitrypsin, and so initiate a process of auto-digestion—a kind of serum autolysis. The work of Jobling and Petersen (1914) and of Bronfenbrenner (1915), among others, is in accord with this possibility; but there are almost insuperable objections to its acceptance as an explanation of the *in vitro* toxification of serum, and still more to the view that it forms the essential mechanism of anaphylactic shock *in vivo*. Thus, there has been an almost universal failure to show any relation between the increase in the toxicity of serum under the influence of a toxifying material and chemical changes indicative of proteolysis (de Kruif and German 1917, Dale 1920*b*, Doerr 1922); while the rapidity of toxification—under favourable conditions a serum may be rendered highly toxic within a few minutes—is hardly compatible with the known behaviour of proteolytic enzyme reactions. Still more is this the case in acute anaphylactic shock. As early as 1908 Wells pointed out the extreme improbability of the view that the minute amount of egg albumin that suffices to produce almost immediate shock in the sensitized guinea-pig could, in the short interval available, undergo proteolysis with the liberation of a toxic dose of degradation products. The substitution of the serum proteins for the antigen as the supposed substrate removes the quantitative difficulty, but greatly increases that introduced by the time factor. We cannot believe in the formation of an antigen-antibody compound, the adsorption by it of a stabilizing serum constituent, and a consequent digestion of the serum proteins, all occurring within a very few minutes. Moreover, substances that produce *in vitro* toxification of serum may fail to produce anaphylactic symptoms when injected intravenously into animals (Dale 1920*b*, Doerr 1922).

The exact nature of the process which underlies the *in vitro* toxification remains obscure; but it appears to be related in some way to the redistribution of the plasma constituents

that occurs during clotting (Novy, de Kruif and Novy 1917, Novy and de Kruif 1917, de Kruif 1917, de Kruif and German 1917).

Anaphylactoid Shock.—Apart altogether from the difficulties referred to above, it is very doubtful how far the acute and fatal reaction that follows the intravenous injection of a toxified serum can be identified with true anaphylactic shock. The resemblances are certainly striking, and it seems certain that common factors are operating; but there are certain differences. At necropsy the emphysema of the lungs may be rather less striking, while œdema and hæmorrhage into the pulmonary tissue are more frequent. For this reason there is general agreement that "anaphylactic" should be replaced by the ambiguous but convenient "anaphylactoid" as a descriptive term for this type of shock, and that "anaphylatoxin" should be replaced by "serotoxin" as a designation for the active agent in toxified serum.

There are, in truth, many agents other than toxified sera that may produce a fatal anaphylactoid reaction when injected intravenously into the guinea-pig. A list of such substances given by Hanzlik and Karsner (1920, 1924) includes a wide variety of organic colloids and of salts of heavy metals. The syndrome produced differs a little from one anaphylactoid agent to another; and with none does it resemble completely and in detail that of true anaphylactic shock. The spasm of the bronchioles—the most dramatic of the anaphylactic reactions in the guinea-pig—is in general a prominent feature, though it may vary in degree. There is, however, a high frequency, with these anaphylactoid reagents, of capillary thromboses and embolism in the lungs.

Among such anaphylactoid reagents—and this has been a source of error in several experiments supposed to support the humoral view—must be included all antisera that contain a high concentration of Forssman antibody (see Doerr and Pick 1913, Taniguchi 1922, Scott 1931). The toxic effect is here due, in part at least, to a direct action of the heterophile antibody on the heterogenetic antigen contained in the guinea-pig's tissues. When the serum is injected by the ordinary intravenous route the first stress of this reaction falls on the endothelium of the lung capillaries, resulting in lesions which appear to be identical with those produced by the serotoxins.

Peptone Shock.—Another anaphylactoid reagent is ordinary peptone (de Waele 1907, Biedl and Kraus 1909, Hirschfelder 1910, Doerr 1914, 1922, Dale 1920*a*, 1929, Manwaring, Clark and Chilcote 1923). The resemblance of peptone shock to true anaphylactic shock is very striking. In the guinea-pig there is the typical contraction of the bronchioles, in the dog the fall in blood pressure and the congestion of the liver. In both there may be found the loss of coagulability of the blood and the multiple small subserous hæmorrhages that are characteristic features of acute anaphylaxis in general. It is probable that peptone, like the serotoxins, acts as a direct endothelial poison (see Dale 1929). In dogs peptone shock is apparently accompanied by a release of heparin (Quick 1936) and histamine (Holmes *et al.* 1941) into the blood. After peptone shock, as after non-fatal anaphylactic shock, dogs remain in a refractory state, but peptone refractoriness depends on the degree of shock suffered, and cannot be induced by sub-shocking doses of peptone (Dragstedt 1943*a*).

Histamine Shock.—Histamine is an amine derived by decarboxylation from histidine. It was isolated from ergot by Barger and Dale (1911) and its pharmacological action has been studied in considerable detail by Dale and his colleagues, and by others (Dale 1913, 1920*a*, *b*, 1929, Dale and Laidlaw 1919, Maunter and Pick 1915, Longcope 1922, Voegtlin and Dyer 1924).

The toxic syndrome produced by histamine reproduces very faithfully several

of the characteristic features of acute anaphylaxis. In the guinea-pig the spasm of the bronchioles is constantly present in its most typical form. In the dog (Maunter and Pick 1915, Dale 1929) the muscular walls of the efferent hepatic veins are very sensitive to histamine ; in response to traces of this substance they constrict and dam back the blood in the capillary spaces of the liver. But there are also quite definite points of difference. The distension of the dog's liver with blood and lymph in anaphylaxis is far more severe and persistent than that produced by histamine. Nor does the blood become incoagulable in histamine poisoning ; but this we should expect if the incoagulability is due to the liberation of heparin.

The importance of these observations lies in the fact that histamine is a relatively simple substance of known chemical constitution, the pharmocological action of which has been studied in considerable detail. It can hardly be a mere coincidence that on intravenous injection it mimics so closely the syndrome produced by the injection of a non-toxic antigen into a sensitized animal.

Summarizing the evidence up to this point we may say that sera may be treated in various ways that render them toxic, in the sense that they produce when injected intravenously into the guinea-pig a syndrome that closely resembles, but is not identical with, that of acute anaphylactic shock. There is, however, no evidence that an " anaphylatoxin " is produced as the *direct* result of an antigen-antibody reaction occurring in the blood stream, nor has any mechanism for the production of such an anaphylatoxin been yet suggested which is compatible with all the known facts. Moreover, many reagents other than toxified sera will produce similar anaphylactoid reactions ; and one reagent of known chemical composition will give rise to some of the most characteristic features of acute shock. It seems clear that the apparent uniformity of the major symptoms of these different *in vivo* reactions is misleading, if we regard it as denoting an identity of underlying mechanism, though we can hardly be mistaken in supposing that some common actor runs through them all. It will be convenient to consider the cellular hypothesis of anaphylactic shock before discussing what this factor is likely to be.

The Cellular Hypothesis.—The essence of this hypothesis is that, for the production of anaphylactic shock, the primary antigen-antibody reaction must occur, not in the blood stream or tissue fluids, but in or on the cells of the animal. Why this cellular reaction should give rise to the striking syndrome that characterizes acute shock is a separate problem that we may consider later.

The earliest experiments made it clear that those procedures that led to a high concentration of antibodies in the circulating blood were not those that produced the anaphylactic state. Repeated injections of antigen into a normal animal lead to a high antibody content but not to hypersensitiveness. In passive sensitization the highest concentration of antibody in the blood occurs immediately after the sensitizing injection of antiserum ; but it is only after the lapse of a latent period, during which most of the antibody has disappeared from the blood stream (Fenyvessy and Freund, see Doerr 1922, Weil 1913), that hypersensitiveness is established.

Such facts as these clearly suggested that " fixed," not " circulating " antibody was concerned in the reaction. But far more decisive support for the cellular hypothesis was derived from experiments carried out with isolated tissues from actively and passively sensitized animals.

Schultz (1910) excised portions of intestine from sensitized guinea-pigs, suspended them in a bath of Ringer's solution, and studied their response to the addition of the specific antigen. He found that such isolated muscle contracted far more vigorously, when the antigen was added to the bath, than did similar preparations from normal animals when submitted to the action of similar amounts of the same foreign protein. These observations were confirmed and greatly extended by Dale (1913), using an improved technique in which one horn of the guinea-pig's uterus was substituted for the intestinal preparation, and this technique has since been used by Dale and his colleagues (Dale 1920*a*, *b*, 1929, Dale and Hartley 1916, Dale and Kellaway 1922), and by Weil (1913–17) in attempts to determine the underlying mechanism of the acute anaphylactic reaction.

The reaction of the sensitized uterine horn is extraordinarily delicate ; a typical contraction may occur after the addition of as little as 1 ml. of a 1 : 10,000,000 dilution of horse serum to a bath containing 150 ml. of Locke's solution. It is also sharply specific ; not only does the uterus removed from a guinea-pig sensitized against horse serum fail to respond to the serum of cat, rabbit, dog or man, but it is possible to sensitize separately against the euglobulin, pseudoglobulin and albumin fractions of horse serum (Dale and Hartley 1916).

All the essential features of anaphylaxis can, indeed, be demonstrated *in vitro*. Uterine horns removed from guinea-pigs sensitized either actively or passively respond specifically to the addition of the specific antigen to the bath of Ringer or Locke solution in which they are suspended. Perfusion of the uterus with warm Ringer solution before removal from the body does not abolish its sensitiveness. After a single maximal response to the addition of a relatively large amount of antigen, followed by a change to fresh Ringer's solution, the uterus no longer responds to the addition of fresh antigen : it has been specifically desensitized. If such a desensitized uterus is again washed, soaked for 2½ hours in a 10 per cent. dilution of the specific antiserum, washed in numerous changes of Ringer's solution, and again tested by the addition of antigen, it will give a typical contraction, showing that it has been passively sensitized *in vitro*. The uteri of normal guinea-pigs may be rendered hypersensitive by prolonged perfusion with diluted serum from anaphylactic or immunized guinea-pigs. This hypersensitiveness is hardly perceptible after 1 hour's perfusion, but it is easily perceptible after 5 hours' perfusion, a period strikingly similar to the latent period in passive sensitization in the living animal. Nevertheless, an almost immediate sensitization of the isolated uterus can be achieved *in vitro*, comparable in speed with that which must precede the anaphylaxis following the almost simultaneous injection of antigen and antibody into the whole animal. Kulka (1942, 1943) records sensitization of a normal uterine strip by an exposure of 1 minute to a solution of antibody, and was able to induce contractions in a normal uterine strip by adding mixtures of antigen and antibody to the surrounding fluid.

A fact of great significance was established by Dale while investigating the response of the uteri from immunized guinea-pigs. These animals had received repeated injections of horse serum increasing in amount. Some of them were injected intraperitoneally with 5 ml. of horse serum but showed no sign of shock. Nevertheless, the uterine horns, removed from other animals of the same series, reacted with a typical contraction on the addition of horse serum to the bath, thus showing that fixed antibody is present in the immune as well as in the hypersensitive animal, and lending strong support to the view that the immune guinea-pig is protected by the excess of antibody in its circulating blood.

The protective function of circulating antibody is clearly illustrated in some of Weil's experiments (see Fig. 267). A series of guinea-pigs were passively sensitized by the intraperitoneal injection of 0·1 ml. of rabbit-v-horse serum, i.e. the serum from a rabbit immunized by repeated injections of horse serum. Three days later one animal received 2 ml. of this antiserum (20 sensitizing doses) and immediately thereafter 0·01 ml. of horse serum (1–2 anaphylactic doses). This guinea-pig showed slight symptoms only. It was killed; its uterus was tested by Dale's technique, and its serum was injected into another normal

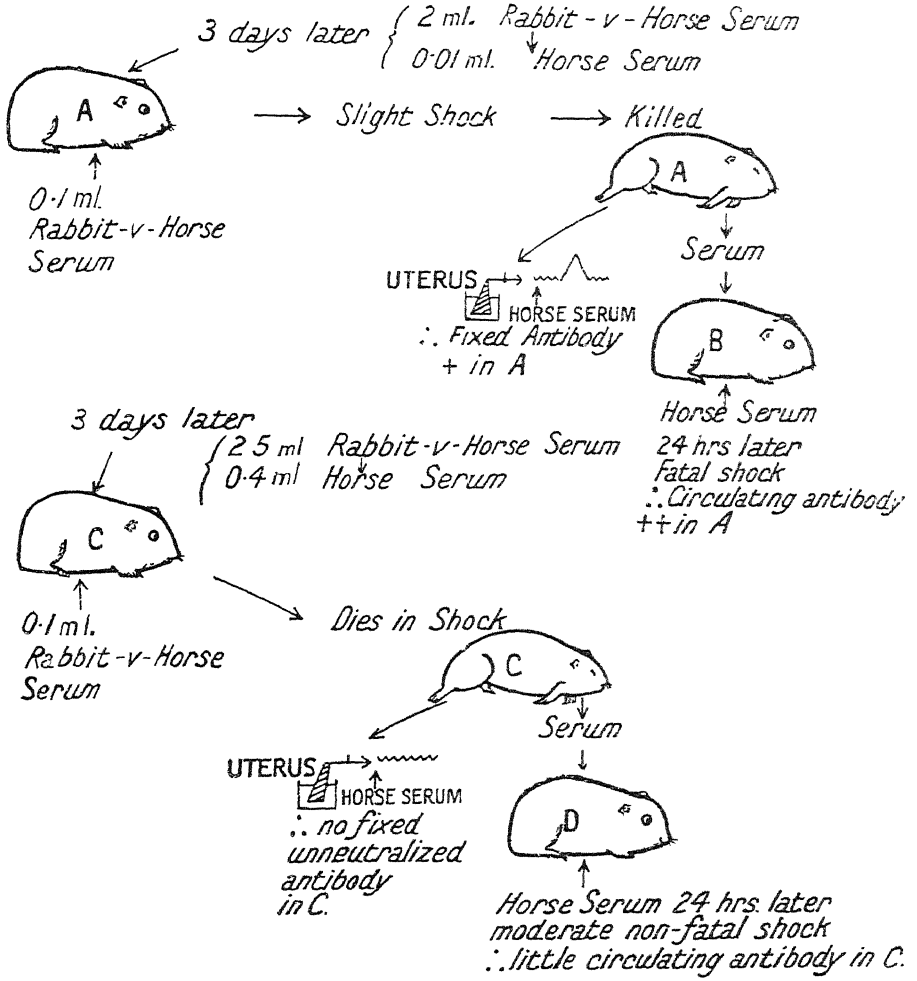

FIG. 267.

guinea-pig which was tested 24 hours later by the injection of horse serum. The uterus of the first animal gave a typical reaction, showing that it had anchored the antibody injected 3 days previously, and that this fixed antibody had not combined to any appreciable extent with the 0·01 ml. of antigen subsequently injected under cover of a protective dose of antibody. The second guinea-pig developed typical shock, showing that a considerable amount of the antibody injected into the first guinea-pig immediately prior to the injection of the antigen had remained unneutralized in the circulation. Another sensitized guinea-pig

of the same series received 2·5 ml. of the rabbit-v-horse serum (25 sensitizing doses) and immediately thereafter 0·4 ml. of horse serum (52 anaphylactic doses). It died in acute shock, showing that the amount of antibody present was not sufficient to protect the cells containing the fixed antibody from this excessive dose of antigen. The uterus, removed immediately after death, showed itself to be desensitized. A normal guinea-pig was injected with the serum of this animal and 24 hours later received an injection of horse serum. It developed moderate symptoms only, showing that the greater part of the circulating antibody in the animal that died of acute shock had been neutralized by the large dose of antigen. It should be noted, however, that serum antibody does not always protect. Morris (1936*a*) records that an excess of antibody injected into sensitized guinea-pigs led to an increase, not a decrease, of sensitivity. Nor must we in all cases attribute the anti-anaphylactic effect of intravenous sera to the presence of antibody in excess. Thus Kellaway and Cowell (1922), Morris (1936*a*), Moldovan and Maier (1941) describe an anti-anaphylactic effect in normal serum, when administered a few minutes before the shocking dose of antigen. According to Moldovan and Maier, the substance responsible for this effect is heat-stable, of low molecular weight, antagonized by pituitrin, and is produced when the reticulo-endothelial system of normal animals is stimulated by injection of colloidal material. They find that the serum of sensitized guinea-pigs is lacking in the shock-inhibitor.

Gordon (1940) records a non-specific inhibitory action of congo red in sensitized guinea-pigs, especially if administered over a period of days before the shocking dose. The mode of action of these non-specific substances is not clear. In the case of congo red, Gordon suggests that it interferes with the absorption of antigen on to sensitized cells.

Taking the evidence as a whole, the different behaviour of the hypersensitive and the "immune" guinea-pig may with some confidence be attributed to a difference in the relative concentration of fixed and circulating antibody.

If, however, we turn to other animals the evidence is more confused (see Dale 1920*b*, Scott 1931); and the observations of Manwaring and his colleagues (1923–28) on acute anaphylaxis in the dog are particularly difficult to fit into the relatively simple picture that we have drawn above. It seems, however, altogether unlikely that the mechanism of acute anaphylaxis differs fundamentally from one animal to another; and it is probable that apparent discrepancies will in time resolve themselves into the expression of secondary divergencies in a reaction of one essential type.

If we accept the view that the cellular responses that characterize acute anaphylaxis are the result of an antigen-antibody reaction occurring on or in the cells, are we to believe that this is the whole story—that it is this reaction in and by itself that affords the stimulus to cellular contraction, or produces all the localized vascular changes? If so, how can we explain the fact that those tissues that play the most dramatic part in acute shock are exactly those that are sensitive to histamine? We can hardly believe that these cells, and these alone, are concerned in the fixation of antibody.

The difficulty would in part be explained if it could be shown, as was suggested by Abel and Kubotka (1919), that histamine itself was produced by some form of protein cleavage within the cell as the result of the injury inflicted by the antigen-antibody reaction; but there is no adequate evidence that such an enzyme action occurs (see Dale 1929).

The Rôle of Histamine in Anaphylaxis.—The evidence for the essential rôle of histamine in anaphylactic shock falls under four heads. Firstly, the likeness between histamine shock and anaphylactic shock, which we have already noted; secondly, the demonstration that tissues contain histamine that can be mobilized by suitable stimuli; thirdly, the demonstration of histamine mobilization during

shock; and fourthly, the suppression of shock by measures that destroy or inhibit histamine or inhibit the reaction.

Lewis (1927), in his classical studies on the reaction of the skin to a localized stimulus or injury, was able to show that the local reddening, due to the dilatation of the minute blood vessels, and the succeeding local wheal, were independent of the local neuro-vascular mechanism, whereas the surrounding flare, due to the dilatation of the neighbouring arterioles, was dependent on a local axon reflex. He concluded that the reddening and the wheal formation were the result of a chemical stimulus provided by some substance liberated from the injured cells; and he found that histamine, alone among the many known substances that he tested, reproduced in complete detail the effects of this cell constituent, which he refers to as the *H-substance*. Dale and his colleagues (see Dale 1929, Dale, Dudley and Thorpe 1927, Harris 1927, Thorpe 1928) showed that histamine is a normal constituent of many different tissues; and the evidence available strongly supports the view that it exists as such during life, and is not formed from some mother-substance after cell-death. Whether it is present in the free uncombined state, in which it is readily diffusible, is more doubtful. There are reasons for believing that it may, in certain circumstances at least, be present, and be liberated from the cell, in loose combination with cell-constituents of high molecular weight and low diffusibility.

The relative histamine content of different tissues is interesting and suggestive. Using a physiological method of assay (see Thorpe 1928, Harris 1927) the lungs have been found to contain between 35 and 75 mgm. of available histamine per kilo, the liver between 2·5 and 6·6 mgm., the skin as a whole about 6 mgm. (24 mgm. in the epidermis and 4 mgm. in the dermis). Other tissues contain much less. The voluntary muscles contain about 1 mgm. per kilo, the testis about 1·8 mgm., the submaxillary gland about 0·5 mgm., and the thyroid about the same.

Histamine is destroyed rapidly in normal blood, a fact which probably accounts for early failures to detect this substance in anaphylactic animals (see Dragstedt and Mead 1935). Dragstedt and Mead (1936*a*) described a histamine-like substance in the blood of dogs after anaphylactic shock. By measuring the normal rate of destruction of histamine in the blood, they calculated the amount present in the animals at the onset of shock, and found it enough to account for the vascular reactions of the shocked animal. The substance was specifically destroyed by the enzyme histaminase (Dragstedt and Mead 1936*b*; see also Code 1939).

Watanabe (1931) obtained some evidence that the histamine content of the lungs of sensitized guinea-pigs was abnormally high, and much less in the lungs of animals after shock. Bartosch, Feldberg and Nagel (1932) noted the appearance of a histamine-like substance in the perfusate of sensitized guinea-pig lungs when antigen was added to the perfusion fluid. This observation was confirmed by a number of workers, and the identity of the substance with histamine more firmly established (see Schild 1937). Increased quantities of the histamine-like substance were also found in the blood of the whole guinea-pig after shock (Simon and Staub 1937, Code 1939). In the rabbit, on the other hand, though anaphylactic shock and histamine shock are similar, a drop in the blood histamine after shock was observed by Rose and Weil (1939). Rabbit's blood, however, is rich in histamine, a fact which led Katz (1940) and Dragstedt, Ramirez de Arellano and Lawton (1940) to test the *in vitro* effect of antigen on the blood of a sensitized rabbit. Both found that histamine was liberated from the leucocytes into the plasma. (See also Rose and Browne 1940.) Dragstedt (1941) suggests that in the intact sensitized rabbit the injection of antigen leads to the accumulation of the histamine-rich leucocytes in the lung (where it is perhaps liberated), and a consequent fall in blood histamine.

There is thus good evidence that cellular injury, whether anaphylactic or, as in peptone shock, anaphylactoid, in type is liable to liberate histamine into the tissues. We do not know in anaphylaxis whether the cells that are injured and

liberate histamine are themselves histamine-sensitive, whether minimal injury may so disturb the internal economy of a cell that it becomes reactive to its own contained histamine, or whether we should locate the injury and liberation of histamine in one type of cell, the response to the liberated histamine in another; these are problems which are not soluble at present. In some cases there are suggestive hints. Isolated plain muscle from the sensitized dog gives no significant response to the specific antigen. Yet the plain muscle of the dog is sensitive to histamine. It would seem that in the dog, as opposed to the guinea-pig, the sensitization to the antigen is limited mainly to the liver.

We may now consider briefly the effect of anti-histamine substances on anaphylactic shock. Histamine is readily destroyed by the enzyme histaminase (Best and McHenry 1930). However, though Karady and Browne (1939) claimed to have protected sensitized guinea-pigs from shock by intravenous injections of the enzyme 15 minutes before the shocking dose, their findings were not subsequently confirmed (Knoll 1940, Rose and Browne 1941, Younger, Freedman and Nungester 1941, Alexander and Bolton 1940). Staub (1939) described an *in vitro* anti-histamine action in a number of synthetic amine bases. One of these, N-phenyl-N-ethyl-N′-diethylethylenediamine, was reported by Wilcox and Seegal (1942) to have inhibited anaphylactic shock in sensitized guinea-pigs.

The administration of sublethal doses of histamine induces a state of increased tolerance to the drug. Farmer (1939) and Karady (1941) claim that histamine desensitization is accompanied by a moderate degree of desensitization to specific anaphylactic shock. Fell and others (1943, Rodney and Fell 1943) immunized rabbits with horse globulin coupled with the pharmacologically inactive *p*-aminobenzoyl histamine, and induced the formation of antibodies whose specificity was partly determined by the histamine. The immunized animals were then sensitized with ovalbumin. As compared with non-immune sensitized controls, there was definite evidence of a reduced liberation of histamine into the blood during shock, and of a reduced skin sensitiveness either to shocking doses of antigen, or to histamine. Immunized guinea-pigs, subsequently sensitized to ovalbumin, were protected to a marked degree against fatal shock. It was considered unlikely that the protection was due to desensitization by histamine liberated from the globulin antigen. As the authors point out, if the protection is due to specific antibodies against histamine, it remains to determine how such antibody could act in anaphylaxis, and yet have no observable effect on the normal histamine metabolism in the body.

The Rôle of Acetyl-choline in Anaphylaxis.—Went and Lissak (1936, 1938) and Martin and Went (1939) have reported that during the perfusion of the heart of a sensitized guinea-pig with antigen solution, a substance resembling choline is liberated from the muscle, and that the heart muscle of sensitized guinea-pigs is more sensitive than normal hearts to the pharmacological action of choline. Went suggested that choline and acetylcholine, as well as histamine, may be liberated from different organs during shock. Wenner and Buhrmester (1937) found acetylcholine in the blood stream of rabbits after shock, but Ratnoff (1939) could not confirm their findings. Kourilsky and his colleagues (1938) detected no acetylcholine in the hæmorrhagic lesions of shocked animals. They noted that acetylcholine produced no hæmorrhages in the tissues on local injection, whereas histamine did so. Nakamura and his colleagues point out that acetylcholine shock and anaphylactic shock have many features in common, and few in common with histamine shock, both in symptomatology and modification by physostigmine, eserine and other drugs. They attributed the main symptoms of anaphylactic shock to acetylcholine liberated as the result of antigen-antibody union in the region of the nerve-endings of the sympathetic system (Nakamura and Takahashi 1938, Nakamura 1941, Chigira 1941). Farber, Pope and Landsteiner (1944) were able regularly to demonstrate histamine in shocked guinea-pig lung; only in shocked heart tissue was acetylcholine in excess of the normal value, and even there the increase was demonstrable only in 10 per cent. of the tests (see also Bender 1944). The evidence

as a whole points to a participation of choline or acetylcholine in shock, but only as a minor factor.

We may then, in general terms, describe the acute anaphylactic reaction as consisting of two different but related effects—cell injury determined by an antigen-antibody reaction occurring in or on those cells by which antibody has been fixed, and a series of secondary effects due to the liberation of various substances among which histamine, or a histamine-like substance, appears to predominate. The varieties of secondary effects are determined by the response of the cells sensitive to histamine and the other substances liberated. Among the cells capable of liberating histamine under the influence of an antigen-antibody reaction, the possible participation of the circulating leucocytes should be noted.

As regards the anaphylactoid reactions, they differ from acute anaphylactic shock in that the cell injury is not determined by an antigen-antibody reaction; they resemble it in that the secondary histamine effect is essentially the same. It should be noted that most of the anaphylactoid reagents, such as toxified sera, do not stimulate contraction of the isolated guinea-pig uterus. This histamine-liberating injury presumably occurs elsewhere when these agents are injected *in vivo*. Peptone, on the other hand, has a direct stimulating effect on plain muscle, which suggests that it initiates a mobilization of histamine.

The complete picture of an anaphylactic or anaphylactoid reaction will thus consist of a description of cellular injury, differing from case to case according to the reagent employed and the susceptibilities of the experimental animal, and a histamine effect, differing from one animal species to another according to the distribution of the histamine-sensitive cells, but common to all reactions in one animal species, by whatever reagents they are caused.

Local Anaphylactic Reactions

Within a year of the original observations of Portier and Richet, and before the phenomenon of acute anaphylactic shock had been submitted to any detailed study, Arthus (1903) described a curious reaction in the rabbit, which was soon recognized as belonging to the same order of exaggerated response to a foreign antigen. Inoculating rabbits subcutaneously with repeated doses of horse serum, he noted that the initial injections were without any detectable effect, but that, as one injection succeeded another with suitable intervals between them, the local reactions became more intense and more persistent. After a few injections the site of inoculation became swollen and œdematous. These local swellings were at first transient, but with each successive injection they lasted longer, with more definite induration, until finally the response took the form of a firm indurated swelling which progressed to a localized necrosis. This altered response was not confined to the tissues in the immediate neighbourhood of the earlier injections. The rabbit, as a whole, had become so sensitized that it reacted in this characteristic and abnormal way to the injection of the specific antigen at any site (see also Seegal, Seegal and Jost 1932, Davidoff, Seegal and Seegal 1932). It may be noted that this reaction, in its typical form, appears to be peculiar to the rabbit. Nicolle (1907) failed to reproduce it in the guinea-pig, and Opie (1924) failed to elicit it in either the guinea-pig or the dog. Dragstedt (1941) suggests that the peculiar susceptibility of the rabbit may be due to the high histamine content of its leucocytes, which, accumulating in the early tissue response to the local injection of antigen, form a rich source of local histamine by the time sensitization has occurred.

HYPERSENSITIVENESS IN MAN

Clinical observations have long been on record containing descriptions of reactions in human subjects that present obvious analogies to the anaphylactic reaction in experimental animals.

Serum Sickness.—It has been known for many years that a proportion of those persons who receive injections of antitoxic or antibacterial serum for prophylactic or therapeutic purposes develop a curious and characteristic condition which has been given the name of " serum sickness." An excellent description of the disease and a detailed discussion of its significance are contained in the monograph of von Pirquet and Schick (1905). The great extension of serum therapy in modern times has provided the data for large-scale surveys of the incidence and kinds of serum sickness (see Park 1921, 1928, Beer 1938, Lyall and Murdick 1938, Davis 1938, Rutstein *et al.* 1941, Kojis 1942). For our immediate purpose we need refer only to the following points.

The reaction must be distinguished from the disturbances of the thermo-regulatory mechanism, and the cardio-vascular reactions which are commoner sequels to the injection of serum. It occurs after primary as well as after subsequent injections. It is in no way related to the antibody content of the injected serum, but is a response to the foreign protein as such, which is usually horse serum. The reaction may occur within 2 hours of the injection of the serum, and up to 24 days after, though an incubation period of 8 to 12 days is commonest. Among the " immediate " reactors, there is often evidence of previous treatment with horse serum. Younger people are more prone than older, though the proneness may reflect the fact that younger persons are more liable to have had previous antiserum treatment, as compared with persons whose youth was passed in an age of less extensive serum therapy. The illness itself is characterized by rashes, especially of an urticarial type and often commencing at the site of the inoculation, by fever, joint pains, slight œdema without albuminuria (or with a mere trace of albumin in the urine), and by a varying degree of glandular swelling usually confined to the regional glands that receive the lymphatics from the site of inoculation. The illness is variable in duration, protean in its symptoms, and seldom of a serious nature, though it may be associated with severe discomfort. It is probably never fatal. The nervous system is affected, though rarely. The commonest lesions occur in the 5th and 6th cervical nerves. Neuritis is followed by flaccid paralyses of the muscles, with a slow and, in the greater proportion of cases, a complete recovery. Both motor and sensory nerves are affected. The neuritis may affect one or many nerves, and in some cases the lesions are more central and may even be cerebral. The neuritis is ascribed to an urticarial œdema of the nervous tissue. It should be noted that these paralyses may follow the injection of other antigenic substances—vaccines and preparations of toxoid (see Kennedy 1929, Allen 1931, Young 1932, Doyle 1933, Ayer 1935, Wilkinson 1937, Bennett 1939, Hughes 1944).

In a tiny minority of cases an entirely different reaction follows the injection of serum, the patient dying within a few minutes with symptoms resembling those of acute anaphylactic shock. Park (1908) records two such cases among 50,000 persons who received serum injections in New York (see also Park 1921, 1928, Vance and Strassman 1942).

Acute anaphylactic shock can also follow the injection of antigens other than serum proteins. There are, for example, a number of cases on record of shock after a second dose of a bacterial toxoid; the peptone used in the preparation of the toxoid appears to have been the responsible agent (see Parish and Oakley 1940).

We may note that processes which destroy the integrity of the antibody globulin molecule in antisera from the horse also reduce their capacity to cause serum reactions. Thus, when proteolytically refined antisera (Chapter 7) are employed,

the incidence of serum sickness and of sensitization to serum sickness, are reported to be greatly reduced (Pöhacker-Fritsch and Siegl 1941, Kojis 1942; see also Coghill *et al.* 1940, Jones and Roberts 1941, Top and Watson 1941).

The Idiosyncrasies.—Another group of reactions, which clearly come into the general category of hypersensitiveness, are the so-called idiosyncrasies, in which certain persons develop a characteristic symptom-complex as the result of natural contact with some particular substance, or range of substances. The substances that may evoke this response are of the most varied nature: in hay fever, pollens of various species; in asthma, pollens, horse dander or the cutaneous débris from other animals; in the food idiosyncrasies, a wide range of different materials; in the drug idiosyncrasies, a whole series of chemical compounds which seem to have no characteristic or common structure.

One of the most striking features of the idiosyncrasies as a group is that—as in the anaphylactic reaction—the symptom-complex bears no relation to the particular type of substance by which it is evoked. In spite of the varied nature of the exciting materials concerned, the syndrome induced shows an essential uniformity; though there are minor differences which seem to depend in the main on the particular route by which the reacting substance gains access to the tissues. It is particularly striking that, in the case of drugs, the response exhibited by the hypersensitive subject—using hypersensitive in this particular sense—bears no relation to the pharmacological action of the drug in question.

The reactions induced may be either local or general. Among the former are the local reaction to the intracutaneous injection of horse serum or to the application to the skin of such a drug as iodoform, the coryza of hay fever and perhaps the associated asthma, and the acute vomiting and gastro-intestinal disturbance that follow the ingestion of a particular food-stuff. Among the latter are the generalized urticarial eruptions or œdema that may follow the administration by any route of a substance to which a person is hypersensitive, the occasional pyrexia, and the asthmatic symptoms that sometimes follow the entry of the exciting substance by a route other than the respiratory tract.

There are obvious points of similarity between this group of reactions on the one hand and anaphylactic hypersensitiveness on the other, but there are also obvious divergencies.

Among the points of similarity we may include the following (see Coca 1920*a*):—

In both cases the reaction is specific. Although the naturally hypersensitive person may react to several different substances the range is usually limited, and may be confined to a single chemical substance. In both cases the type of response is essentially the same for a single animal species irrespective of the nature of the exciting substance.

Among the features that have been held to differentiate between the two conditions are the following. The exciting agent in anaphylaxis is always an antigenic substance; the exciting agent in human hypersensitiveness is often non-antigenic. Anaphylactic hypersensitiveness is induced by the injection of a sensitizing dose of antigen; hypersensitiveness in man is often exhibited upon first contact with the exciting agent. The anaphylactic state, apart from congenital passive anaphylaxis, is not a heritable condition; natural human hypersensitiveness shows a definite tendency to run in families, though the hypersensitiveness is often exhibited towards different substances in parents and offspring. Specific desensitization is far more easily demonstrated in anaphylaxis than in hypersensitiveness.

Taking these points of difference *seriatim* we may attempt to assess their significance in the light of the evidence now available. Coca and his colleagues, who would regard the differences between the two conditions as sufficient to justify a formal separation into different categories, employ the term *atopy* to denote the natural hypersensitive state, and the term *atopen* to denote the exciting agent (see Coca and Cooke 1923). We may define our first problem as the determination of the differences between atopens and antigens.

Atopens and Antigens.—It is certain that many substances are at the same time antigenic and atopic. Horse serum forms an excellent example, though we should note that Coca and Cooke separate serum sickness from the true atopies. If, however, we confine ourselves to the more typical atopens we still find that a single substance commonly displays both types of activity.

Alexander (1924) found that guinea-pigs could be rendered anaphylactic to rye pollen, though he could not induce the formation of precipitating or complement-fixing antibodies in detectable amount. Parker (1924) reports the production of precipitins for ragweed pollen in rabbits and guinea-pigs, and Ramsden (1926) obtained similar results. Walzer and Grove (1925) showed that the pollens of timothy-grass and ragweed have definite antigenic properties, since both induce the anaphylactic state in guinea-pigs, demonstrable either by intravenous injection or by Dale's technique. They note, however, that sensitization with pollens is far more difficult and uncertain than with such an antigen as horse serum, and they failed to demonstrate precipitins in the serum of the sensitized animals. Caulfeild and his colleagues (1926) prepared various fractions from ragweed, timothy-grass and birch pollens, and obtained with them active and, in some cases, passive sensitization. Ramsden (1926) demonstrated both active and passive sensitization of guinea-pigs to pollen. Longcope and others (1925, 1927) have demonstrated the active sensitization of guinea-pigs to extracts of horse dander, and have succeeded in specifically desensitizing such animals by the usual procedures. Spies and his colleagues have fractionated both cotton seed and kapok seed, and find a number of components capable of sensitizing and shocking experimental animals. The active components are mainly protein in nature, though associated in some instances with carbohydrate. It is noteworthy that the degree of the antigenic relationships between the two seeds in the main reflected the observed degree of cross-reactivity of the two as atopens in sensitized persons (Spies *et al.* 1939, 1940, Coulson and Spies 1943, Coulson *et al.* 1943, 1944, see also Newell 1942). There seems little doubt that many of the reagents that have been classed as typical atopens have a definite antigenic action.

There is, of course, no doubt at all that many of the substances that function as atopens—for example many drugs—are non-protein in nature and are certainly not antigenic in the full sense. Moreover, it has been found (Grove and Coca 1925) that the removal of all proteins and other detectable nitrogenous substances from extracts of pollen, or of house dust, does not cause any appreciable loss of atopic activity, as tested by intracutaneous inoculation in susceptible persons. On the other hand, the tryptic digestion of the proteins of horse dander, or of the green pea, caused a loss of atopic activity corresponding with the loss of protein.

The fact that non-protein substances can excite a specific response in the hypersensitive person cannot, however, be taken as a proof that antigens and atopens differ in any essential respect. We have seen that many haptens, when injected intravenously into actively or passively sensitized guinea-pigs, will induce acute anaphylactic shock, so that it would be in no way surprising if a fundamentally

similar reaction were produced in naturally sensitive persons by contact with antigenic components of a similar kind.

There remain instances of drug idiosyncrasies that are not so readily explicable along these lines, since the chemical structure of the exciting agent is not of the relatively complex kind which characterizes those haptens that are capable of inducing acute shock in a sensitized animal.

Recent observations have, however, indicated a possible mechanism by which such simple compounds might come to function as complete or partial antigens. It has been found that animals may be sensitized by the injection of atoxyl and serum, or even of arsenical compounds alone (see Klopstock and Selter 1929, Mayer and Sulzberger 1931, Sulzberger and Mayer 1931); and it seems probable (Landsteiner and Levine 1930) that in such cases a preliminary union occurs between the simple arsenical compounds and some serum or tissue protein, with the formation of an effective antigenic complex. In later studies Landsteiner and Jacobs (1936) sensitized guinea-pigs with neoarsphenamine, and induced shock by the intravenous injection of guinea-pig serum mixed with arsphenamine, or arsphenamine alone. Jacobs (1932) succeeded in sensitizing guinea-pigs to iodinated sera by injecting them with guinea-pig serum mixed with Lugol's iodine solution, and suggested that a similar mechanism might be involved in the development of iodine sensitiveness in man. Horsfall (1934) injected formolized rabbit serum into rabbits, and found that the animals developed skin sensitivity to uncombined formaldehyde. Landsteiner was able to induce both skin sensitivity and anaphylactic sensitization by the intracutaneous injection of aromatic substances like picryl chloride and dinitrochlorobenzene (Landsteiner and Jacob 1936, Landsteiner and Chase 1937) and non-aromatic substances like diazomethane and mustard oil (Landsteiner and di Somma 1938). These substances are all highly reactive and capable of forming conjugates with tissue proteins, and are also known to induce dermatitis or other forms of hypersensitivity in man (see, for example, Wedroff 1932; see also Landsteiner and Chase 1939, 1940*b*). From a study of the sensitizing action of tetryl (trinitrophenylmethylnitramine) in the skin of guinea-pigs, Gell (1944) concluded that this substance also acted by forming a picryl protein in certain tissues; though there was evidence that not all compounds of tetryl and guinea-pig protein would stimulate sensitivity, and that sensitivity was not necessarily associated with the presence of circulating antibodies to picryl protein.

Para-phenylenediamine also induces sensitivity when applied to the skin of guinea-pigs, and Nitti, Bovet and Depierre (1937) record an interesting series of observations on the specificity of the sensitization with regard to the structure of the substance. Thus, the corresponding *ortho*- and *meta*-compounds would not sensitize, and substitution of SO_2NH_2, $—CH_3$ or —OH groups for one of the $—NH_2$ groups entirely destroyed the allergic capacity of the *para*-compound. Various other substitutions decreased or enhanced both activity and specificity, in a manner which recalls the high degree of dependence of antigenic specificity on chemical structure (see Chapter 7).

Active and Passive Sensitization in Man.—The second criterion that has been accorded differential significance is the mode of sensitization. There is no question that human hypersensitiveness occurs naturally and apart from any known previous contact with the particular antigen to which the sensitive subject reacts, just as the "natural" antibodies may be found in persons who, so far as we can tell, have never been infected with or immunized against the particular bacterium on which their sera react.

There is, however, good evidence that this condition frequently arises as the result of active sensitization.

Hooker (1924) tested a large number of persons by the intracutaneous injection of horse serum before and after they had been immunized by the injection of toxin-anti-

toxin mixtures. Of 367 persons tested before immunization 308 failed to react to horse serum. Of these, 100 were found to be Schick-positive and were immunized by toxin-antitoxin injections. On retesting these 100 persons at a later date, 66 gave positive reactions to horse serum. Park (1924) carried out a similar series of observations, in which he tested the sensitiveness to horse serum of immunized and non-immunized groups of children. He found that 84 of 116 children who had received toxin-antitoxin injections reacted positively to horse serum, while of 90 children who had not been immunized 45 were sensitive, giving a difference of 22·5 per cent. between the two groups. Other observers (Cowie 1914, Longcope and Rackeman 1918, Gordon and Creswell 1929, Mackenzie 1924) have obtained results that point in the same direction. It would appear that the injection of horse serum significantly increases the percentage of sensitive persons in a sample of the normal population. As we have already noted (p. 1119), the intradermal injection of pneumococcal polysaccharides may induce a specific skin-sensitivity, so that this effect is not limited to protein substances.

Again (see von Pirquet and Schick 1905), while the serum sickness that develops in a naturally hypersensitive person, apart from previous sensitization, is almost always of the delayed type described above, a proportion of those cases that occur in persons who have received previous injections of horse serum show a characteristic acceleration of the response. In some cases the localized œdema, the generalized urticaria, the febrile reaction and all the symptoms of severe serum sickness may develop within 24 hours.

The most striking evidence in favour of the view that experimental anaphylaxis and natural hypersensitiveness depend on essentially similar mechanisms has, perhaps, been provided by the demonstration that hypersensitiveness to a particular atopen or antigen can be passively transferred from one person to another, since this clearly places human hypersensitiveness with anaphylaxis in the category of the antigen-antibody reactions.

Ramirez de Arellano (1920) reported a case of sensitiveness to horse dander. The man was employed as donor in the transfusion of an anæmic patient who received 600 ml. of his blood. The recipient, who gave no history of such an idiosyncrasy, thereafter developed marked hypersensitiveness to horse dander. The evidential value of this case is somewhat lessened by the fact that the same donor was used in another transfusion without rendering the recipient hypersensitive. Again, serum sickness is associated with the appearance of precipitins in the blood, either during the sickness, or after the height of the disease (Longcope and Rackemann 1918, Jones and Fleisher 1932, DeGara and Bullowa 1942), and transfer of the serum will induce a passive anaphylactic state in the guinea-pig. Recently Karelitz and Stempien (1942) produced " passive serum sickness " by injecting into persons, already treated with therapeutic horse antisera, the serum of other persons who were convalescent from serum sickness.

An observation that has provided a basis for the experimental study of passive sensitization in man was recorded by Prausnitz and Küstner in 1921. Küstner himself was markedly sensitive to the cooked flesh of certain fish. Using an extract of cooked fish as antigen these observers failed to demonstrate the presence of precipitins in Küstner's serum, nor could they produce passive sensitization of guinea-pigs. If, however, a little of Küstner's serum was injected into the skin of a normal person and the antigen was injected into the same site 24 hours later, a marked local reaction was produced. This reaction did not occur if the antigen and the serum were injected simultaneously, a finding strikingly analogous to the latent period in the passive anaphylactic sensitization of the guinea-pig. The

Prausnitz-Küstner reaction has been used extensively for the study of passive sensitization in man. Wright and Hopkins (1941) describe a more sensitive reaction, depending on "reversed" passive sensitization, in which the skin site is injected first with antigen, and, 24 hours later, with the serum.

The detailed study of this passive atopic sensitization has been taken up by Coca and his colleagues and by other investigators. Coca and Grove (1925) gave the name *atopic reagins* to the antibodies present in the serum of naturally hypersensitive persons, through the agency of which the specific hypersensitiveness can be passively transferred to the skin of normal non-sensitive persons. They record that these reagins have been demonstrated in the serum of all those subjects of hay fever or of asthma in whom the reaction to the intradermal injection of the specific atopen is positive. They find, however, that not all normal skins are receptive, about 11 per cent. failing to react at all, and some 5 per cent. giving slight or doubtful reactions. The remaining 84 per cent. are fully receptive, and the local passive sensitization lasts for at least 4 weeks once it has been established. They find that the reagin may be neutralized by the specific atopen in the test tube, but that it gives no precipitin reaction *in vitro*, nor will it induce passive anaphylaxis in the guinea-pig. In a control series of experiments they noted that the normal human skin could not be passively sensitized to egg white or to ragweed-pollen with rabbit antisera, although these contained specific precipitins. Exactly similar phenomena have, however, been noted in the case of passive anaphylaxis—neither horse antisera nor chicken antisera are effective in the passive anaphylactic sensitization of the guinea-pig, though antisera prepared in the rabbit are highly efficient from this point of view.

Clarke and Gallagher (1926) give a very clear-cut demonstration of the latent period in passive atopic sensitization and of the *in vivo* neutralization of reagin by atopen without the production of any tissue reaction. They injected 0·05 ml. of atopen into one area of skin, and 5 minutes later they injected 0·05 ml. of reagin-containing serum into the same site and 0·05 ml. of the same serum into a second site some distance from the first. No reaction occurred after these injections, showing that the union in the tissues of atopen and reagin under conditions that give no time for the preliminary fixation of the reagin does not produce the typical response. Next day each site was reinjected with the same quantity of atopen. At the second site, where no atopen had previously been injected, a typical reaction occurred. At the first site no obvious response was elicited, showing that the reagin had been neutralized by the atopen that was present when the sensitizing injection was given.

Levine and Coca (1927) found that there was a proportional relationship between the degree of sensitivity of the skin and the reagin content of the serum in 33 cases of hay fever.

Reagins and Antibodies.—The observations quoted above do not suggest that any clear separation can be made between these two types of antibody. It is true that reagins may be demonstrated in sera that give no precipitation with the specific antigen; but, as we have seen, passive anaphylaxis may be induced with sera in which no precipitins can be detected. Again, sera that contain antibodies may not induce passive sensitization. Karelitz and Glorig (1943) record an instance of a serum from a patient convalescent from serum sickness, which was rich in anti-horse precipitin but which, on intravenous injection into a normal subject, failed to react with an antigen injected locally in the skin. Therapeutic horse serum, however, is not a single defined antigen, and we cannot exclude the possibility of two different antibodies, only one of which is capable of passive sensitization. It is by no means clear, therefore, that reagins and precipitins are different antibodies; the apparent qualitative differences may in reality be quantitative—as they appear to be in anaphylaxis—depending on a difference in delicacy between

the *in vivo* and *in vitro* tests. De Besche (1918), for instance, has reported the presence of precipitins in the serum of a considerable proportion of a small group of asthmatics who were sensitive to the proteins of the horse, cat, dog or cow. He notes that patients who showed the presence of precipitins at one time might fail to do so at another. The antibodies appeared to fluctuate above and below the level at which they were demonstrable *in vitro*. Moreover, the precipitin reaction is relatively insensitive for the detection of antibody (see Chapter 7). Cannon and Marshall (1941) devised a more sensitive test for antibody, using the agglutination of collodion particles coated with antigen. By this means, they found a marked parallelism between serum antibody and sensitivity to the Arthus phenomenon in rabbits, both before and after desensitization.

Otto and Adelsberger (1931) have recorded a careful series of observations on the relation between the atopic reagins and the anaphylactic antibodies. They note that the typical reagin, as exemplified in the sera of persons sensitive to horse dander, is extremely effective in the transference of specific sensitivity to a localized area of the normal human skin. It is less effective in sensitizing the skin of the guinea-pig, and quite ineffective in sensitizing that animal to anaphylactic shock. The sera of persons suffering from serum sickness, or of those who have been injected with horse serum without suffering from the clinical disease, are effective—though somewhat less effective—in the transference of sensitivity to the normal human skin. They are far more effective in sensitizing the guinea-pig's skin ; and are not infrequently effective in inducing generalized anaphylactic sensitization. Anti-horse sera, prepared in rabbits or guinea-pigs, are relatively—but not entirely—ineffective in the transference of sensitivity to the human skin, but are uniformly effective in inducing passive anaphylaxis in the guinea-pig. Again, Caulfeild, Brown and Waters (1937) were able to induce the same specific sensitization to extract of ragweed pollen in the skin of a normal person by serum from a hypersensitive person, and by serum from a guinea-pig immunized with ragweed extract.

It is possible that the passive transfer of reagins is most easily accomplished when the donor and recipient of the serum are biologically related. Straus (1937), for instance, found that *rhesus* monkeys were readily sensitized by the injection of human sera containing reagins.

The evidence as a whole suggests minor differences in the antibodies with which these various workers have been concerned—differences perhaps connected with the proteins in antisera obtained from different animal species rather than with the active grouping of the antibody ; but there seems no adequate reason for regarding reagins and anaphylactic antibodies as belonging to essentially different types. *Atopens* and *reagins* might well give place to *antigens* and *antibodies* in immunological nomenclature, except where some convenient term is required to denote the way in which an antigen or antibody is functioning at a particular time.

The substances that induce natural hypersensitivity are complex. The various manifestations of hypersensitivity to a substance may therefore be the result of interactions between more than one kind of antibody and perhaps more than one kind of antigen. We have already seen that antibodies vary in their powers of inducing passive sensitization, and that one antigenic preparation may have conspicuously different powers of sensitizing on the one hand and inducing an allergic reaction on the other. The different reactivities of sera from hypersensitive persons may alter independently of one another.

For instance, Schmidt and Lippard (1937), who measured the capacity of " hypersensitive " sera to neutralize the corresponding antigen so that it would no longer elicit a

Prausnitz-Küstner reaction, and the capacity to sensitize the skin of normal persons, found that the latter was much more readily destroyed than the former, by heating to 56° C. In this case we cannot tell whether a single antibody was altered in respect of two activities or whether two antibodies were concerned. There is, however, evidence that more than one type of antibody is concerned in certain manifestations of hypersensitivity. Cooke (1941) showed that the desensitization of persons sensitive to certain pollens was accompanied by the appearance in the serum of an antibody capable of neutralizing the pollen antigens. This " blocking " antibody appeared to be distinct from the reagin upon which the passive transfer of hypersensitivity depended. For example, Sherman, Hampton and Cooke (1940) found that blocking antibodies in pregnant mothers were transmitted to the child *via* the placenta, but that reagins were not. However, neither Cooke nor Scully and Rackmann (1941) could find any correlation between the titre of blocking antibody and the state of desensitization of the patient. Loveless (1940, 1941, 1942, 1943), on the other hand, believes that the reagin is responsible for sensitivity, and the blocking antibody for the desensitized state. She finds this to be produced specifically by injection of pollen ; it is non-sensitizing, and readily diffusible, and differs from reagin in being relatively thermostable, withstanding exposure to 56° C. for 24 hours.

The Genetic Factor in Anaphylaxis and Hypersensitiveness.—The third character that has been held to differentiate human hypersensitiveness from anaphylaxis is concerned with the part played by inheritance in the two conditions. There is evidence (Cooke and Veer 1916, Coca 1920*a*, Spain and Cooke 1924, Clarke, Donnally and Coca 1928) that human hypersensitiveness tends to run in families. There is at present no evidence that the anaphylactic state, as induced in the sensitized guinea-pig, occurs naturally or is determined by genetic factors. Does this indicate any essential difference in the nature of the two phenomena ?

Even if we accepted the premises as warranting such a conclusion we should require much more evidence than we have before we accepted the second premise as valid. Anaphylaxis in its usual experimental form is, of course, never inherited ; since one of the necessary conditions for its study is that the injection of the antigen into the unsensitized animal shall not produce shock, *i.e.*, the experimental animal selected must not be naturally sensitive to the antigen under test. Whether there are any cases in which the injection of an antigen into an animal that has not been artificially sensitized produces typical anaphylactic shock, demonstrably due to an antigen-antibody reaction, we do not know, because no systematic search has ever been made. In the absence of such knowledge we cannot tell what part inheritance plays in the natural anaphylactic state, if that state occurs. As Doerr (1922) points out, we have for obvious reasons studied natural hypersensitiveness in man and anaphylaxis in experimental animals. It is at least possible that the differences noted are referable in large part to the different fields that have been selected for study.

With regard to the inheritance of human hypersensitiveness we have already noted (see Cooke and Veer 1916, Spain and Cooke 1924) that the genetic factor appears to be concerned with a tendency to develop atopic hypersensitiveness in general, rather than a sensitiveness to any one atopen in particular. It appears to be unusual to find that parents and offspring, or several members of the same family, are all hypersensitive to the same substance ; one may respond to ragweed pollen, another to horse dander, another to cat hairs, and so on. It has also been noted (Clarke, Donnally and Coca 1928) that the type of reaction to atopic substances in general appears to be in some degree inherited ; the tendency to develop asthmatic symptoms, for instance, being particularly frequent in certain families.

Landsteiner and Chase (1940*a*) report that guinea-pigs can by breeding be separated

into strains of high and low susceptibility to sensitization by dinitrochlorobenzene, or to the atopens of poison ivy, thus affording one indication of a similarity between man and experimental animals in a heritable tendency to develop hypersensitivity.

There seem insufficient grounds for postulating an essential difference between anaphylaxis and hypersensitiveness on the premises of our present knowledge of the influence of genetic factors in the two conditions.

Desensitization in Hypersensitiveness and Idiosyncrasy.

Fourthly, some observers, and particularly Coca (1920*b*), would lay great stress on the difficulty of desensitization in the sensitive human subject as compared with its relative ease and certainty in the anaphylactic animal. While admitting that a degree of lessened sensitivity to natural contact with the specific atopen may be attained in a hypersensitive person by suitably graded injections, Coca points out that the further administration of the atopen by subcutaneous or intracutaneous inoculation will always demonstrate the persistence of the hypersensitive state.

It seems doubtful, however, whether this criterion has any greater differential value as between the atopic and anaphylactic states than those we have discussed above. It is true that desensitization may readily be demonstrated in the anaphylactic guinea-pig ; but even here it depends on a strict observance of the necessary quantitative and time relationships, as may be seen in many of Weil's experiments. In other species the problem is far less simple ; it is for instance notoriously difficult to desensitize the rabbit.

In the hypersensitive human subject, as in the experimentally sensitized animal, the available evidence indicates that desensitization induces a temporary change in the immunological balance of the tissues, with a subsequent reversion to the hypersensitive state (see Vallery-Radot *et al.* 1936, Adelsberger 1936, Gernez 1936).

We cannot of course apply the results obtained in our animal experiments, without modification, to our clinical problems. The relief of a case of hay fever or the desensitization of a serum-sensitive patient as a preliminary to the administration of antitoxin, demands the application of a technique that can be elaborated only on a basis of empirical trial, and which may or may not be successful. This does not, however, justify the conclusion that there is any essential qualitative difference in the underlying mechanism.

ALLERGIC REACTIONS IN BACTERIAL INFECTIONS

The term *allergy* is almost impossible to define. Here we are using it in a loose, but widely accepted sense to cover a group of reactions characterized by a heightened or accelerated response to a particular type of antigen, irrespective of the balance of harm, or benefit, that the altered response confers on the allergic host.

All the phenomena of hypersensitiveness could obviously be included under this general label. In the present section we are concerned with those instances in which an allergic state develops in relation to a bacterial infection.

It has already been noted that bacterial haptens may induce acute anaphylactic shock in a sensitized guinea-pig ; but before discussing allergic reactions in the wider sense we may refer briefly to the question of anaphylactic sensitization with bacterial antigens.

The available data may be summarized by stating that active sensitization has been induced with various bacterial antigens and passive sensitization with the corresponding antibodies as demonstrated by the occurrence of acute shock (Rosenau and Anderson 1907, Kraus and Doerr 1908, Holobut 1909, Kraus and Admiridzibi 1910, Zinsser and Parker 1917, Tomesik and Kurotchkin 1928, Lancefield 1928, Enders 1929, Avery and Tillet 1929), or by Dale's technique with the isolated uterus (Zinsser and Parker 1917, Zinsser and Mallory 1924, Tomesik and Kurotchkin 1928). The reactions are specific and desensitization can be demonstrated. Sensitization to bacterial antigens cannot, however, be produced with the same ease as can sensitization to such antigens as horse serum or egg white. A single injection of bacteria frequently fails to produce any demonstrable sensitization, and the most successful results have been obtained by giving repeated small injections of antigen, followed by an interval of three weeks or so before the intravenous injection of the test dose, which should be relatively large. A technical difficulty in work of this kind is introduced by the fact that many of the bacterial suspensions employed are themselves toxic when administered in any considerable dose, and the symptoms that develop in normal animals after the injection of massive doses of bacteria or bacterial products may be very similar to anaphylactic shock. The difference in the response of normal and of sensitized animals may, therefore, be relatively difficult to detect.

Turning to those instances in which specific sensitization occurs during the course of a bacterial infection—the type of hypersensitiveness with which we are most closely concerned—the classical example of an allergic response to a non-living bacterial antigen is afforded by the tuberculin reaction in its various forms.

This experimental allergic reaction is readily demonstrated in the guinea-pig. The injection into a normal guinea-pig of 2 ml. of Koch's old tuberculin—a culture of tubercle bacilli in 5 per cent. glycerine broth, grown for 6–8 weeks at 38° C., concentrated to 1/10th volume at 100° C., and freed from bacilli by filtration through a clay or kieselguhr candle—has little effect. But the injection of 0·01 ml. into a guinea-pig in the 8th or 10th week of tuberculous infection may kill it within a few hours. At necropsy, supposing the injection to have been given subcutaneously, the site of inoculation is found to be very congested, dark red or almost violet in colour. The focal glands are swollen and congested, the liver and spleen show on their surface numerous dark red spots, particularly in the neighbourhood of the multiple tuberculous lesions which are commonly present. Microscopically these red spots are seen to consist of enormously dilated capillaries. Thus the tuberculin produces a local reaction at the site of inoculation, numerous scattered focal reactions in the immediate neighbourhood of pre-existing tuberculous foci, and a rapidly fatal toxæmic effect, probably secondary to the widespread focal reactions.

This fatal generalized tuberculin reaction in the guinea-pig exemplifies the allergic response in its severest form. The development of hypersensitiveness in an infected animal may, however, be demonstrated quite as clearly by means of the localized reaction that follows the intracutaneous injection of 0·2 ml. of a high dilution (1 : 800 to 1 : 4,000) of tuberculin (see Römer and Joseph 1909, 1910, Lewis and Aronson 1923, Eagleton and Baxter 1923). For further details with regard to the tuberculin reaction, and its diagnostic use in human and veterinary medicine, see Chapter 59.

We have so far been concerned with the allergic response to a non-living antigenic material; but there is abundant evidence that the sensitized tissues respond differently from the non-sensitized to contact with living bacteria. Here again, the classical example is afforded by Koch's observations on experimental tuberculosis (Koch 1891).

When a normal guinea-pig is injected subcutaneously with living tubercle bacilli, a localized nodule appears at the site of inoculation after 10–14 days. This nodule increases in size, involves the skin, and undergoes necrosis, leaving an indurated ulcer that persists until the animal's death. Meanwhile there occurs the characteristic lymphatic spread of

infection, affecting first the regional lymphatic glands and later the more remote tissues and organs. But if living tubercle bacilli are injected into a guinea-pig that is already infected with tuberculosis of some weeks' duration the result is quite different. On the 1st or 2nd day following the reinoculation the site of injection shows an area of acute superficial inflammation 0·5–1 cm. in diameter, without the formation of any nodule in the underlying subcutaneous tissue. Next day the affected area of skin is found to be necrotic, and finally it sloughs, leaving a flat, shallow ulcer which undergoes rapid healing. The regional lymph glands are not affected; and there is no evidence of the spread of infection from the localized focus caused by the second inoculation. This rapid and energetic response does not, in this case, confer any permanent benefit on the guinea-pig, for it is destined to die from the primary infection; but it affords a striking example of a reaction that betrays at one and the same time the character of hypersensitiveness and of immunity.

Although tuberculosis happens to afford the classical illustration of allergy developing as the result of infection, there are numberless other examples. There is, indeed, little doubt that an increased sensitivity, associated with an increased vigour of response, is of frequent, perhaps of almost constant, occurrence at one stage or another of every infective disease; and it is very probable that this sensitization plays a part in pathogenesis, particularly in subacute or chronic infections.

Bacterial and Anaphylactic Hypersensitiveness and Immunity.

Among the many issues raised by the phenomena of bacterial hypersensitiveness, two may be considered as outstanding—namely, the relation between the bacterial and the anaphylactic types of hypersensitiveness, and the value of specific hypersensitiveness in defence against bacterial infection.

Zinsser (1921) was the first to distinguish the two types of hypersensitiveness. In guinea-pigs sensitized to the tubercle bacillus, he found that susceptibility to anaphylactic shock by bacillary proteins could exist independently of tuberculin skin-reactivity. The distinction was confirmed for the tubercle bacillus, and demonstrated in hypersensitiveness to pneumococci and streptococci (Mueller 1926, Enders 1929, Zinsser and Grinnell 1925, 1927, Dochez and Sherman 1925). The local skin reaction of the tuberculin type reaches its maximum slowly, after a lag of several hours, while the anaphylactic reaction takes place soon after injection of the antigen. Moreover, the tuberculin type of sensitization is best induced only after contact of the tissues with bacteria and is as a rule not induced by soluble bacterial products. Dienes (1927), however, made the interesting observation that if tuberculous guinea-pigs were sensitized with a soluble antigen like ovalbumin, the skin reactions to ovalbumin were of the delayed tuberculin type, and that this change in reactivity was most easily elicited when the ovalbumin was injected directly into a tuberculous focus. In the light of the adjuvant action of dead tubercle bacilli on the antigenicity of various substances discussed on p. 1116 it is perhaps legitimate to suggest that this result follows from an enhancement of the degree and type of antibody response, and not from a peculiarity of the antigen.

The significance of these facts is not immediately clear, but they indicate that induction of the tuberculin type of sensitivity is associated with active cellular tissue reactions in the body of the animal. The importance of the cellular element in bacterial hypersensitivity is emphasized by the work of Rich and others, who showed that whereas tissue cultures from animals in the anaphylactic hypersensitive state were unaffected by the addition of antigen, those from tuberculin-sensitive animals were killed by the addition of tuberculin (Rich and Lewis 1932, Aronson 1931, 1933, Moen and Swift 1936). Moen (1936, 1937) records a similar lethal effect with extracts of Group C streptococci on growing cultures of tissues from guinea-pigs sensitized by infection with the cocci. Rich (1941) suggests that the anaphylactic reaction depends primarily on vascular damage. When, for

example, antigen is applied to the normally non-vascular cornea of a sensitized animal, little reaction occurs; but if the cornea is vascularized by previous non-specific inflammation, the application of antigen results in a violent reaction (see Rich and Follis 1940). In bacterial hypersensitiveness, on the other hand, the reaction appears to depend on direct damage to the tissue cells.

The close association of bacterial hypersensitiveness with the tissues themselves is emphasized by the fact that passive transfer has seldom been satisfactorily achieved. In this respect, too, it differs from anaphylactic hypersensitivity, though here again, as we have seen, passive transfer is not always demonstrable.

The distinction between the two types of hypersensitiveness is of some importance in considering the rôle of the hypersensitive reactions in infection, but before proceeding to discuss that issue, it should be noted that the distinction is by no means necessarily fundamental. In the immunological sense both types are specific, but the antigenic analysis of the sensitizing substances is by no means complete, and as Bronfenbrenner (1940) points out, the peculiarities of bacterial hypersensitivity may be referable to the antigenic complexity of the bacteria and to the state of aggregation of the component antigens. The distinction is most marked with tuberculin sensitivity, but with other bacterial antigens it is less so. For instance, we have ourselves induced responses of the slowly-developing tuberculin-type in guinea-pigs sensitized by intradermal injections of the soluble antigens of *Br. melitensis*.

The rôle of hypersensitiveness in infection is a controversial matter which has centred mainly round the problem of immunity in tuberculous infection. The reader is referred to the full discussion of this subject in Chapter 59. We shall limit ourselves here to a few general observations (for an extensive review of the matter, see Rich 1941). As Rich points out, in the hypersensitive animal a bland antigenic substance behaves as though it were an acutely irritant toxin, inducing reactions of varying intensity, from mild inflammation to complete local necrosis when given locally, and fatal reactions when given systemically. *A priori*, then, we might expect that an animal hypersensitive to a bacterium would be more susceptible to infection than a normal animal, on account of the enhanced toxic action of the bacterial antigens. On the other hand, it has been observed (Chapter 53) that a tissue which is inflamed is in some circumstances capable of localizing a bacterial invasion more effectively than normal tissue.

Has the exaggerated inflammatory response to bacteria in the tissues of a hypersensitive animal any protective action? The answer to this question is complicated by the fact that a hypersensitive animal is often an immune animal, and what we infer to be a protective effect of the hypersensitive reaction may be due to an immune process independent of the sensitized state. Therefore the demonstration of a local immune response in a hypersensitive animal, even at an early stage in the process of immunization when a general immunity cannot be demonstrated (see, for example, Seastone 1939, Schlesinger and McBroom 1940, Foley 1944), is not a sure indication that the hypersensitive and the immune reactions are identical. We may circumvent this difficulty by comparing the resistance to infection of hypersensitive *and* immune animals, with that of immune desensitized animals. The validity of the comparison will depend on the degree to which our tests of desensitization—usually skin tests—really indicate desensitization of the whole animal. DeGara and Angevine (1943), for example, sensitized rabbits with killed pneumococci or streptococci, and tested the sensitivity of liver, spleen and

skin by direct injection of the corresponding bacterial suspension; there was no correlation between the degree of organ and skin reactions. But if we accept the usual criteria of desensitization, there is in some cases good evidence that hypersensitiveness does not by itself confer any immunity.

Thus Morris (1936*b*) found that injection of anti-Friedländer Type B serum into guinea-pigs rendered them both hypersensitive and immune, and that desensitization with Friedländer specific carbohydrate did not significantly reduce their immunity. Rich (1930) pointed out that the local inflammatory response to infection in the hypersensitive animal would develop after the bacteria had reached the tissues, whereas the protective effect of non-specific inflammation is manifest only when bacteria are introduced into already established lesions. If hypersensitive reactions independent of the bacterial antigens are induced in experimental infections, they appear to have little effect. Cannon and Hartley (1938), for example, injected a mixture of virulent pneumococci and ovalbumin into the skin of rabbits which were (*a*) immunized against pneumococci and sensitized to ovalbumin, (*b*) sensitized to ovalbumin, and (*c*) untreated. In groups (*b*) and (*c*) the progress of the disease was similar, ending in a septicæmic death in 48 hours; the group (*a*) animals survived. The local hypersensitive inflammatory reaction in group (*b*) animals did not affect their local resistance to the pneumococci.

It may be noted that general anaphylactic shock induced by non-bacterial antigens appears to affect the outcome of infections or intoxication either little or adversely. Weissberger (1937) reports a prolongation of experimental streptococcal bacteræmia in sensitized rabbits given a simultaneous injection of horse serum. Otto and Schafer (1937) on the other hand, found that sublethal anaphylactic shock had little influence on the course of a *Salm. enteritidis* infection of guinea-pigs that had been established for 2 days.

The allergy of infection, then, may be regarded as a state of partial immunity, as well as of increased sensitivity; and the all-inclusive classification of Doerr (1922) who would place acute anaphylaxis, natural hypersensitiveness and immunity in a single generic group, with sub-groups clearly marked by certain features but shading into each other when the focus of attention is shifted from the obvious manifestation to the underlying mechanism, offers a reasonable as well as a coherent picture of the phenomena that we have considered in this chapter.

So far as our present knowledge goes it seems very probable that anaphylaxis, hypersensitiveness, and immunity of the type dependent on specific antibodies, all result from the working of a single underlying mechanism, the character of the total reaction being determined in each particular case by a variety of secondary factors. Anaphylactic shock, for instance, is an experimental curiosity of high informative value to the student of immunity but not of any obvious significance in determining the survival or extinction of a species during the course of its evolution. The sudden introduction of a foreign antigenic substance into the circulating blood is not an event that is likely to menace any living thing, unless it is subjected to intentional human interference. It is neither paradoxical nor surprising that a mechanism, which in natural circumstances tends directly towards immunity, should react to the disadvantage of its possessor when exposed to a stimulus that formed no part of the environment in which it was evolved. Nevertheless, in accepting this picture of the essential unity of these phenomena we must not commit ourselves to a belief that the naturally occurring manifestations of allergy are necessarily beneficial or even harmless to the species of animal displaying them.

The existence of a certain biological feature in an animal is not a sufficient guarantee that the feature has necessarily contributed to the survival of the species. An adverse feature might well be preserved, provided that the intensity

of selection with respect to it was sufficiently low. The only reliable tests of biological value are those made directly on the species as it is now established in the animal world.

Infection-Immunity.

This is as convenient a place as any in which to mention a conception that is often found in current bacteriological literature—the hypothesis that there is a kind of immunity that is associated with existing, but not with past infection. In its extreme form this conception suggests that so long as an infection with a particular bacterial parasite exists, even though that infection is latent, the host will be immune to reinfection with that particular bacterium, but that once the host's tissues are freed altogether from the infecting parasite susceptibility will return.

We have already noted Koch's observation that a guinea-pig behaves differently towards a primary and a secondary infection with living tubercle bacilli. The studies of many subsequent workers have confirmed and greatly extended his findings, and have shown quite clearly that a subacute or chronic tuberculous infection is associated with a considerable resistance to reinfection.

Significant evidence bearing on the problem of infection-immunity has been obtained during the study of experimental syphilis in the rabbit. In this infection it is possible, by administering an adequate dose of neosalvarsan, or of one of the related arsenical drugs, to cure the initial infection and observe the effect of so doing on the resistance of the rabbit to reinfection.

A syphilitic keratitis may be induced in the rabbit by the injection of *Trep. pallidum* into the anterior chamber of the eye (see Bertarelli 1906, 1907, 1908), a chancre may be produced by injection into the skin of the scrotum (Tomasczewski 1910), and a characteristic lesion follows injection into the testicle (Parodi 1907).

When an infected rabbit is reinoculated with the same strain of *Trep. pallidum* after a relatively short interval a local chancre does not develop (Truffi 1910); but reinfection with a different strain may induce a typical local lesion (Kolle and Schlossberger 1926). Brown and Pearce (1921) infected a number of rabbits and treated some of them with arsphenamine shortly after the development of the primary chancre. Five days later these rabbits were injected with the same strain of *Trep. pallidum*. Most of the treated animals developed chancres. The untreated animals did not.

Kolle (1922, 1924) treated rabbits with neosalvarsan at various stages of infection. He found that rabbits treated within about 6 weeks after the initial infection usually responded to a subsequent injection by developing a new chancre. When treatment was delayed beyond this point, reinfection seldom gave rise to a chancre. When treatment was delayed for about 3 months a new chancre could very rarely be produced. Rabbits that were treated and reinfected at long intervals after the primary infection (75–250 days) were not, however, completely resistant to reinfection (see Kolle and Prigge 1927, 1929). Tissue extracts from treated rabbits that had not been reinfected were non-infective for normal rabbits, but similar extracts from treated and reinfected rabbits gave rise to characteristic lesions, showing that the spirochætes had gained access to the tissues and were presumably multiplying in them, at least to a limited extent. On these grounds Kolle and his colleagues maintain that the immunity to reinfectioin dispayed by rabbits that have been treated in this way is only a " chancre immunity." The

exact significance of this term is a little dubious. We have noted many examples of a partial antibacterial immunity in which bacteria may persist for long periods in the tissues without giving rise to any of the lesions that they produce in non-immunized animals. Moreover, the evidence suggests that a more complete immunity against *Trep. pallidum* may be induced under optimal conditions. Uhlenhuth and Grossmann (1928) treated syphilitic rabbits with neosalvarsan 107 to 506 days after the primary infection. Attempted reinfection 3 to 10 months after treatment gave rise to no obvious lesions; and in only 4 of 11 rabbits could spirochætes be demonstrated in the tissues. (For a more detailed discussion and further references see Chapter 81.)

In summary, we may say that immunity to reinfection appears to be established within a short time after the appearance of the initial lesion. At this stage the maintenance of immunity depends on the maintenance of infection; complete chemotherapeutic cure is followed by a return of susceptibility. But after a longer period of infection a partial immunity is established that may persist after complete chemotherapeutic cure; and, after still longer periods of infection, a complete immunity may be established that is independent of the persistence of infection.

Whether it is necessary to assume the existence of some mechanism other than those we have considered in this and in preceding chapters, in order to account for the immunity to reinfection— or, as it is more appropriately termed, to " superinfection "—during the early stages of the initial infection, is a question that cannot yet be answered. We may, at least, note that this resistance to superinfection appears to be type-specific. As regards the resistance developed during the later stages of infection, it seems highly probable that it can be accounted for by a slow acquirement of an immunity of the usual antibacterial type.

SUMMARY

(1) Acute anaphylactic shock may be produced by inoculating into an animal any antigen to which it has previously been sensitized. The symptoms and lesions associated with shock in any particular case are determined by the anatomical and functional peculiarities of the species of animal employed, not by the character of the antigenic material injected.

(2) Sensitization is specific. It may be induced either actively or passively, and hence must depend, at least in part, on some form of antigen-antibody reaction.

(3) Active sensitization is induced—in the case of such an animal as the guinea-pig and such an antigen as horse serum—by a single minimal injection of antigen. After this injection there follows a latent period during which hypersensitiveness develops, and during this period no further injections of antigen must be given. Once the anaphylactic state has been actively induced it lasts for months or years.

(4) Passive sensitization is induced by the injection into a normal animal of the serum from a sensitized or from an immunized animal—that is by any serum containing the specific antibody. There is a correlation between the antibody content of a serum and its effectiveness as a sensitizing agent; and for this reason the serum of an immune animal is more effective (*i.e.*, sensitizes in smaller doses) than the serum of a hypersensitive animal. The anaphylactic state that is induced by the injection of an antibody-containing serum takes some hours to develop. To ensure typical shock the shocking dose of antigen should not be injected until

8 to 24 hours have elapsed after the injection of the antiserum. During this latent period the antibodies have, for the most part, disappeared from the blood and become fixed on or in the tissue cells. The anaphylactic state when passively induced passes off in a few days or weeks.

(5) To produce typical shock in either an actively or passively sensitized animal, the shocking dose of antigen must be introduced into the blood stream rapidly and in adequate, though not necessarily in large amount. Intravenous injection gives the most consistent results, and in many cases is the only route by which typical shock can be induced.

(6) The injection of haptens, or partial antigens, fails to induce active sensitization, just as it fails to induce active immunity. Complex haptens, such as the bacterial polysaccharides, will induce acute shock when injected into an animal actively sensitized by the injection of the corresponding full antigen, or passively sensitized by the injection of a specific antiserum. Less complex haptens will neither induce active sensitization nor induce shock in a sensitized animal; but when injected into such an animal they will inhibit the induction of shock by the corresponding antigen. In a sensitized animal antigens and haptens behave *in vivo* as they behave in the precipitin reaction *in vitro*. Certain simple, highly reactive organic compounds are capable of inducing hypersensitiveness, by combining with and modifying the proteins of the body to form antigenic complexes.

(7) The sensitized animal may be desensitized by the injection of the specific antigen in amounts too small to induce acute shock or by a route that ensures slow absorption so that there is no rapid transport to the circulating blood.

(8) The anaphylactic state can be demonstrated in an isolated tissue or organ as well as in the animal as a whole; thus, the uterus of a sensitized guinea-pig reacts *in vitro* to contact with the antigen employed in sensitization.

(9) The balance of experimental evidence is strongly in favour of the view that the anaphylactic response is the result of an antigen-antibody reaction occurring on or in the cells that have removed the antibody from the blood and in some way fixed it themselves. The anaphylactic state is associated with the presence of fixed antibody and the absence of circulating antibody, though in the rabbit, and occasionally in other animals, the white cells of the blood themselves are sensitive to shock. The immune state is associated with the presence of circulating antibody in a concentration sufficient to protect the fixed antibody that is also present.

The difference between the anaphylactic and immune state is quantitative rather than qualitative, depending upon the balance between circulating and fixed antibody.

(10) Many of the most dramatic features of the syndrome of anaphylactic shock are the result not of the antigen-antibody reaction itself but of the liberation, among other substances, of histamine by the injured cells, and the secondary response of the histamine-sensitive cells throughout the body.

(11) A great variety of substances, when injected intravenously, may give rise to a syndrome resembling, in many but not in all particulars, that of anaphylactic shock. These reactions are spoken of as anaphylactoid reactions. The resemblance is not due to any similarity in the underlying mechanism, but to the fact that, in each case, cellular injury is followed by the liberation of histamine and other substances, and this by the characteristic syndrome of histamine shock.

(12) Apart from acute anaphylactic shock there are other examples of hypersensitiveness, among them the natural idiosyncrasies that have been observed in

man to contact with particular materials, such as pollens, horse serum, horse dander, and certain drugs.

(13) In spite of obvious superficial differences between this condition and experimental anaphylaxis in the guinea-pig, the knowledge that has been gained in recent years—and particularly the demonstration that skin sensitivity to these atopic substances can be passively transferred—has lent support to the view that the underlying mechanism is essentially the same.

(14) Specific hypersensitiveness may also develop in the course of natural or experimental bacterial infection. This type of hypersensitiveness—which is sometimes referred to as *allergy*—is characterized by an accelerated and exaggerated reaction to contact with the infecting bacterium or its products. It partakes of the character of hypersensitiveness in these respects. It partakes of the character of immunity in that the allergic reaction is often associated with the localization of infection. This type of reaction may sometimes be demonstrated in animals that have been immunized by the injection of bacteria or bacterial products, as well as in animals that are suffering from an active or quiescent infection. It may be an important factor in the development of natural or artificial immunity.

(15) Acute anaphylaxis, natural hypersensitiveness, the allergic response and specific antibacterial immunity would appear to depend on the same fundamental mechanism—the union of an antigen with its specific antibody. The differences between them depend on the nature of the antigen concerned (living parasite, toxic substance or intrinsically inert material), the nature of the animal into whose tissues it penetrates, the rate and route of penetration, the distribution of the antibody in the animal's tissues and body fluids, the secondary effects of the primary cellular reactions, and a variety of other factors.

CHAPTER 52

CERTAIN NON-SPECIFIC MECHANISMS IN GENERAL IMMUNITY

THE integrated protective mechanisms which we have described in the preceding chapters are specific in their action. When fully established, by nature or by art, they increase the resistance of the body against some particular bacterial infection, not against bacterial infections in general. In the present chapter we shall consider certain mechanisms from which this element of specificity is absent.

β-Lysins, Leukins and Plakins.—Among the earliest records of experimental immunity are a series of observations on anthrax infection, which establish clearly the presence in the serum of certain animal species of bactericidal substances different in kind from the bactericidal complex formed of specific sensitizer and complement. Thus the serum of the rat is actively bactericidal for the anthrax bacillus, and this activity remains after heating the serum at a temperature of 56–60° C. for 30–40 minutes (von Behring 1889, 1892, Malvoz 1902, Pirenne 1904). The name *β-lysins* has since been applied to these relatively thermostable bactericidal serum constituents.

Another series of observations, dating from the same early period, have shown that similar thermostable bactericidal substances can be extracted from suspensions of polymorphonuclear leucocytes. Like the β-lysins these *leukins* are restricted in their range of activity, some bacterial species, in particular the spore-bearing aerobes such as *B. anthracis* and *B. subtilis*, being highly sensitive to their action, other species being relatively or entirely resistant. There is some divergence of evidence with regard to the susceptibility or insusceptibility of different bacteria, and it seems possible that the leukins derived from one animal species may differ in this respect from those derived from another. Nor can it be said that there is yet any certainty as to whether the β-lysins and leukins are relatively simple substances, or complex systems like serum complement, with its end-piece, mid-piece and third and fourth components. Pettersson (1936) distinguishes two components of β-lysin action, the β-lysin and an "activating" substance. Unlike the specific α-lysins, which are absorbed by bacteria and "activated" by complement, the "activating" substances of the β-lysin, not the thermostable β-lysin, are absorbed by susceptible bacteria. (See Hahn 1895, Schattenfroh 1897, 1899. Pettersson 1906, 1908*a*, *b*, Hiss 1908, Hiss and Zinsser 1908, Zinsser and Hiss 1908, Schneider 1909, Zinsser 1910, Kling 1910, Weil 1911, Blum 1922, Haussmann 1925, Mackie and Finkelstein 1932, Mackie *et al.* 1932, Gordon and Wood 1937, Hjorth 1937, Gratia and Goreckzy 1938, Oldfelt 1942.)

There are observations which suggest that substances with a general similarity to leukins may be extracted from blood platelets (see Pettersson, above, Gruber and Futaki 1907, Barreau 1909), and these have been called *plakins*. It is not certain what relation the β-lysins bear to the leukins or to the plakins. There are apparent

differences in thermostability—the β-lysins are inactivated at temperatures between 65° and 70° C., the leukins not below 75° C. But these differences have hardly been established with sufficient sharpness, or with sufficient regard to possible effects of differences in the containing medium, to be accepted as a clear differential criterion. It seems certain, however, that many animal species may contain no demonstrable β-lysins in their serum, although leukins may readily be derived from their leucocytes.

Our present knowledge may be summarized by the statement that there exist in the normal sera of certain animal species thermostable bactericidal substances which are non-specific in their action, in the sense in which immunological specificity is generally understood—though their range of activity is limited by the varying sensitiveness of different bacterial species—and which are not increased in amount as the result of immunization. Bactericidal substances having very similar properties may be extracted from leucocytes and perhaps from blood platelets.

The relation of these substances to effective immunity is by no means clear. To take the case of anthrax, the relatively resistant rat has β-lysins in its serum, so has the susceptible rabbit, while the relatively resistant dog has none (see Ledingham 1922).

The significance of the leukins and plakins is still more difficult to assess. They are not identical with leucocytic enzymes (see Fleischmann 1928) though the participation of extracellular enzymes of this kind in leukin action cannot be excluded. That the leukins—using that term for the moment as a generic name for the antibacterial substances present in or derived from leucocytes—play some part in resistance to infection, seems a highly probable assumption; but we do not know whether their rôle is primary or secondary, nor how it is related to the defence mechanisms that we have considered in more detail above.

We may note, in this connection, an observation by Buxton and Torrey (1906) which suggests that the polymorphonuclear cells play a significant rôle as bactericidal agents, even when they are not concerned in the primary phagocytic reaction. The injection of typhoid bacilli into the peritoneal cavity of the rabbit is followed by the rapid deposition of a large proportion of the injected bacteria on the surface of the omentum. Here they are in part destroyed by extracellular lysis, in part ingested by the omental histiocytes. During the first 4–6 hours the polymorphonuclear cells play little if any part in the events on the omental surface, but after that interval there is a marked and increasing polymorphonuclear reaction which varies in intensity in different animals, and the fate of the rabbit appears to depend in part on the successful mobilization of the polymorphonuclear cells. When they collect rapidly and in large numbers the clearance of typhoid bacilli is complete, and the animal recovers. When they are scanty or slow in arrival secondary centres of bacterial multiplication appear, and the animal dies with a generalized bacteræmic infection. These observations have not been repeated in detail by later observers, and are not therefore established on a sufficiently broad basis to allow of any general induction; but they are clearly suggestive.

Variations in the Phagocytic Power of the Leucocytes.—We have seen that one animal differs from another in the phagocytic power of its whole blood and that this difference is determined, at least in part, by the presence or relative concentration of sensitizing antibodies, the opsonins or bacteriotropins, whose action is increased in effectiveness by the normal serum complement. This opsonizing action is specific, so far as the sensitizing antibody is concerned, and may be increased

or induced *de novo* as the result of specific immunization. But the phagocytic activity of the leucocytes, as was first shown clearly by Shattock and Dudgeon (1908), is itself variable. Leucocytes from different persons, and particularly from persons suffering from various infections, show a significant difference in their ability to ingest not only various bacteria, but also inert particles, such as melanin. The latter observation is of importance, since it indicates that such variations in phagocytic activity are independent of the nature of the phagocytable object (see also Glynn and Cox 1909–10, Boughton 1910, Rosenow 1910, Hektoen 1911, Wright 1931).

Lysozyme.—In Chapter 45 we referred to the bactericidal substance described by Fleming under the name of lysozyme and noted that, in high concentration, it has some bactericidal effect on pathogenic bacteria as well as on those non-pathogenic organisms that are particularly susceptible to its action. What part this substance plays in the defence mechanisms of the tissues it is, at the moment, impossible to say.

Induced Variations in the Non-specific Bactericidal Power of the Blood.—This leads us to a consideration, necessarily brief, of the possibility of inducing an effective immunity by increasing the non-specific bactericidal mechanisms of the cells and fluids of the body. Wright and his collaborators (see Wright, Colebrook and Storer 1923, Wright 1931, 1942) have been active in exploring this field. Using specially devised *in vitro* methods of testing the bactericidal power of the whole blood, they have found that the addition of living or killed bacterial suspensions to blood in the test tube, or the injection of similar suspensions into the living animal, results in a very rapid increase in bactericidal power. This increase they attribute, in greater part, to the liberation by the leucocytes of directly bactericidal substances, in lesser part to increased opsonic power. Although this response is not specific—in the sense that there need be no antigenic relationship between the bacterium employed to induce the response and the bacterium against which the bactericidal effect is exerted—some bacterial suspensions have been found to provide a more effective stimulus than others.

This increased bactericidal power is developed with great rapidity—within a few minutes or hours—and is relatively transient, lasting at most for a period of days. It may be induced by a wide variety of stimuli.

Thus Prausnitz and Meissner (1925) record an increase in the bactericidal power of the whole blood after the injection of yatren and aolan. Fleming (1926) records a characteristic response after the injection of salt solutions into rabbits, or after the injection of nuclein (1928). Colebrook, Eidenow and Hill (1924) have recorded a similar response after exposure to ultra-violet light or to dark heat, and also after the application of a mustard plaster (see also Wenger 1938).

In some instances, at least, this temporary increase in the bactericidal power of the blood would seem to be due to, or associated with, an increase in the opsonic power of the serum (see Ledingham and Bulloch 1906, Bedson 1915). Thus, Bedson found that an injection of nuclein was followed by an increase in the normal opsonic action, which was detectable within 20–30 minutes, was still demonstrable after 24 hours, but then rapidly faded.

It must be emphasized that the *in vitro* mixtures of blood and bacteria employed in these investigations are exceedingly complex, and may be susceptible to a number of unrecognized environmental factors that are not operative *in vivo*. The point is well illustrated in the careful study of Fuller, Colebrook and Maxted (1939), who found that

the bactericidal power of human blood, though not of rabbit or mouse blood, was almost completely suppressed if CO_2 was allowed to accumulate in the tubes containing the blood-bacterium mixture under study. (See also Tillett 1937, Tillett and Stock 1937, Miles and Misra 1938.)

The value of this reaction as a protective mechanism is exceedingly difficult to determine. It may be concerned in some, at least, of those instances in which a temporary, or trivial, increase in resistance has been observed to follow a procedure which could not have resulted in the production of specific antibodies.

H. D. Wright, for example, has noted that rabbits may show an increased resistance to the intravenous injection of virulent pneumococci within 5 hours of the injection of a killed suspension of the same organism, a time interval too short to permit of antibody production. Similarly, Teague and McWilliams (1917) report that the intravenous injection of killed typhoid bacilli into rabbits is followed, within 24 hours, by a slight resistance to the injection of living bacilli. In other instances, the injection of a killed suspension of a given bacterium has been observed to induce a slight, or transient, increase in resistance to some antigenically unrelated organism (H. D. Wright 1927, Nukada and Arifuku 1931, and many others). The triviality, or transitoriness, of this non-specific increase in resistance should be stressed ; and in this connection we may recall the effect of non-specific immunization in protecting mice against natural infection with *Salm. typhi-murium* (see Table 73, p. 1056). The limited mean survival time of control unvaccinated mice, in an infected herd, was $26{\cdot}26 \pm 0{\cdot}641$ days, that of mice vaccinated with *Staphylococcus anreus* (an entirely unrelated organism) was $29{\cdot}86 \pm 0{\cdot}714$ days. Mice immunized with a specific vaccine lived on the average $35{\cdot}31 \pm 0{\cdot}884$ days. The difference between the non-specifically immunized and the control mice was trivial, barely attaining statistical significance, but two other non-specific vaccines gave a closely similar result, while a third, not included in Table 73, gave no protection at all.

Cowan (1939) immunized rabbits with *Past. pseudotuberculosis* and found that the rate of disappearance from the blood of intravenously injected *Staph. aureus*, both immediately after injection and after establishment of the secondary bacteræmia (see p. 1047) was greater than that in normal animals, and equal to that in rabbits immunized with *Staph. aureus* vaccines. In view of the complete antigenic dissimilarity of the pasteurella and the staphylococcus, this effect is clearly non-specific. In this connection we may note that Day (1942, 1944) reports an increased immunity of mice to pneumococcal infection by inoculation with extracts of a wide variety of cocci and bacilli. Day, however, regards the immunity as induced by a common antigen. We also find in naturally occurring disease instances of apparently non-specific stimulation of antibacterial mechanisms which may be analogous to the phenomena discussed above. Thus Wulff (1934), Tillett (1937) and Hjorth (1937) describe a marked increase in the bactericidal properties of serum that occurs in man during fever, decreasing to normal with convalescence from the pyrexial disease. According to Hjorth, the effect is due to substances resembling β-lysins. A similar substance may be responsible for the marked anti-staphylococcal activity of tuberculous pleural effusions recorded by Tobler and Pinner (1943).

Taking the evidence as a whole, it would seem that the increase in resistance afforded by non-specific stimulants of this class are for the most too slight, too transient, or both, to play any significant part in prophylaxis against infection. Whether they can be exploited therapeutically is a different problem.

The Shwartzman Phenomenon.

In the preceding paragraphs we have considered various reactions that are associated with a non-specific increase in resistance. In concluding this chapter it will be convenient to refer briefly to an experimental procedure that is associated

with a localized and non-specific increase in sensitivity. Shwartzman (1928, 1929*a*, *b*, 1931, 1932, 1933) has described a curious phenomenon that has become known by his name, and has been studied in considerable detail by a number of other workers (see Gratia and Linz 1931, 1932, Gross 1931, Peck and Sobotka 1931, Gratia, 1932, Peck 1933, 1934, Freund 1934*a*, *b*, Freund and Smith 1934, Freund and Hosmer 1935, Gerber 1936, Ogata 1936, Shwartzman 1936*a*, *b*, Witebsky and Neter 1936, Giuffré 1937, Shwartzman *et al.* 1937, 1938, Morell and Shwartzman 1938, Alechinsky 1938, 1939, Weir 1938, Ayo 1943).

If a rabbit is injected intradermally with a small amount of a filtrate of a culture of *Salm. typhi*, and 24 hours later is injected intravenously with the same filtrate, the intravenous injection is followed, within a few hours, by the development of a hæmorrhagic lesion at the site of the intradermal injection. It is not, however, necessary that the same organism should be used for the intradermal injection and for the subsequent intravenous injection, or that the organisms used for the two injections should be antigenically related. Filtrates from, or suspensions of, a variety of bacteria will sensitize the skin to the intravenous injection of an equally wide variety of bacteria or bacterial filtrates. Not all bacteria contain effective sensitizing substances, nor is the local sensitizing effect the result of a simple inflammatory reaction. Thus (Shwartzman 1928), the injection of uninoculated culture media, of turpentine or of filtrates of various strains of streptococci, failed to sensitize the skin to the subsequent intravenous injection of filtrates of typhoid cultures. The sensitizing or, as Shwartzman prefers to call them, the " preparatory " substances are thermostable, antigenic, of relatively large particle size and often closely associated if not identical with the " complete antigens " or endotoxins of coliform and salmonella bacilli (see, for example, Iványovics 1936). Purified preparatory substances are said to produce no detectable change in the tissues. Not all Gram-negative bacteria contain preparatory substances (see Witebsky and Salm 1937, Wise and Kerby 1943). Nevertheless, the vascular endothelium is in some way altered by the preparations so that the intravenous " provoking " dose causes severe hæmorrhage and necrosis in the prepared site. The range of provocative substances is much wider than the range of preparatory substances, and includes starch, agar, preparations of bacteria that are incapable of " preparing " the tissues, and animal sera. If an animal is anaphylactically sensitive to the preparatory substance, the preparatory effect is enhanced (Angevine and DeGara 1941); if it is anaphylactically sensitive to the provoking substance, the Shwartzman reaction is enhanced; but the Shwartzman reaction is neither anaphylactic nor is it related to the formation in sera of the toxic substances discussed in Chapter 51 under anaphylatoxins (Shwartzman 1937). Organs other than the skin, particularly the kidney, can be " prepared " by Shwartzman substances, and a similar though general hæmorrhagic reaction can be induced in rabbits by an intravenous preparation followed by an intravenous provocative dose (Sanarelli 1924; see Alechinsky 1939). It is of some interest that young animals are relatively refractory, both as regards preparation and provocation.

Cohen and Moolten (1943) record a number of experiments on the rôle of preparatory factor and provocative factor in experimental infections of rabbits with a strain of *F. necrophorus*. A virulent strain yielded both factors, and an avirulent strain only the preparatory factor. In rabbits infected intratracheally with the avirulent strain, fatal infection could be induced by the intravenous injection, 24 hours later, of provocative factor derived either from the virulent strain, or from an unrelated organism like the meningococcus. Though the results clearly suggest that the two factors may be concerned in the genesis of an infective lesion, it is not clear in what way pathogenesis is related to phenomena elicited, as the Shwartzman reaction is, by the arbitrary intravenous injection of a bacterial fraction 24 hours after the onset of infection.

The possibility that in natural infections there may be local alterations in the reactivity of tissues, particularly of vascular tissues, induced non-specifically by substances of bacterial

origin, cannot be overlooked in our attempts to analyse the phenomena of resistance to infection. But aside from a possible connection between hæmorrhagic phenomena in certain chronic infections in man (see Shwartzman, Klemperer and Gerber 1936) it is at present impossible to say what part this mechanism plays in natural infection and resistance, or in artificial immunization.

SUMMARY

(1) In addition to the specific factors that determine antibacterial immunity, there are certain non-specific factors which appear to play some part in the reaction of the tissues to invading bacteria. The exact significance of these factors, and their relation to the general defence mechanism, are at the moment doubtful.

(2) Among these factors are certain thermostable bacteriolysins—the β-lysins—which are present in the sera of certain animal species. Their bactericidal action is limited to particular bacterial species, and it seems doubtful whether they confer an effective immunity even against these. They are not increased in amount as the result of immunization though they may be increased by non-specific stimuli.

(3) Bactericidal substances may be extracted from leucocytes (the leukins) and perhaps from blood platelets (the plakins). These substances bear many resemblances to the β-lysins, and appear to be even more thermostable. They probably play some part in antibacterial immunity, but what that part is remains, at the moment, an unsolved problem.

(4) Leucocytes vary in their phagocytic activity, and it seems likely that such variations may be induced in response to infection, and perhaps to immunization.

(5) Various non-specific stimuli are capable of inducing a rapid but transient increase in the bactericidal power of the blood, probably determined by some of the factors referred to above. The resulting increase in resistance is too slight, and too temporary, to be of practical prophylactic value. Non-specific stimuli are in some circumstances able to increase the resistance of the animal as a whole, but the increase is small compared with that induced by specific immunization.

(6) The phenomenon described by Shwartzman provides an example of non-specific sensitization.

CHAPTER 53

LOCAL IMMUNITY

THE defence mechanisms with which we have hitherto been concerned have for the most part been generally effective throughout the tissues of the host; and by whatever route bacteria or their products gain access to the tissues these mechanisms will tend to protect the body as a whole.

Another type of immunity may be conceived, confined to one particular area of the body, or to one particular kind of tissue. In Chapter 45 we have discussed certain mechanisms that hinder the access of bacteria to the tissues, many of which, like the lysozyme in the conjunctival sac, or the acidity of the gastric juice, are functions of a particular locality in the body. We may distinguish these from the mechanisms of local immunity which we consider in this chapter, by assuming that they act on the infecting organism before it actually invades the tissues. It will be clear, nevertheless, that the distinction, though convenient, is arbitrary, for the hindering mechanisms may in fact be located in the tissues; and even if their action, like that of gastric juice, takes place manifestly outside the tissues, the effect is ultimately dependent on local tissue function. We must, therefore, be prepared if necessary to accept an "external" hindering mechanism as an expression of a true local immunity, though we shall in the meantime confine ourselves to manifestations of resistance within the tissues.

A heightened local resistance of this kind may or may not be associated with a significant increase in the resistance of the body as a whole; moreover, it may depend on a local variation in the response of a generalized defence mechanism; or upon the reaction of special tissues or types of cell in the area under consideration. There has been a tendency to confuse the issue of local versus general immunity by an inadequate definition of the problem to be solved. The concept of a local immunity as such has been imperfectly separated from hypotheses regarding the mechanisms on which it depends. In some cases the term has been used as though it implied a tissue or cellular immunity, not conditioned by humoral factors. In others there has been a failure to distinguish clearly between specific and non-specific effects. It will simplify discussion if we consider the available evidence from each point of view in turn.

What evidence is there for the existence of a local as opposed to a general immunity?

As long ago as 1887 Meierowitsch (1888) noted that rabbits which had recovered from an experimental attack of erysipelas were resistant to subsequent inoculations of the causative streptococcus during periods up to 2 months. This observation was confirmed by many later workers, and Gromakowsky (1895) noted that animals

which had become resistant to a local cutaneous inoculation did not always withstand an intraperitoneal inoculation.

This phenomenon was studied in much greater detail by Cobbett and Melsome (1895, 1898). They concluded, on the basis of a considerable series of experiments, that an attack of erysipelas in the rabbit completely protects the area of skin affected against a subsequent inoculation of the specific streptococcus; ; while on the rest of the body it confers an immunity which is usually less marked and is sometimes entirely absent. They noted also that, when streptococci were inoculated into the skin of a rabbit's ear after the subsidence in that ear of an attack of erysipelas, an inflammatory reaction quickly appeared but subsided before the typical erysipelatous lesion had made any appreciable progress in a control rabbit. This rapid but transitory inflammatory reaction was most marked in ears that had been locally immunized, less marked in ears that shared in a general protection. Gay and Rhodes (1922) concluded from a study of the same problem that a rabbit which had recovered from an attack of erysipelas was completely protected against subsequent intracutaneous injections of the causative streptococcus, irrespective of its exact locality, for a period of at least 3 months. They were unable to obtain a similar immunity by the intracutaneous injection of cultures killed by heat or by alcohol. Immunity against intracutaneous inoculation was not associated with immunity against intravenous inoculation ; while immunization by the intravenous route was found to afford more protection against subsequent intravenous inoculation than against intracutaneous inoculation. Rivers (1925) carried out a series of experiments in which rabbits were given repeated intracutaneous injections of living hæmolytic streptococci derived from a case of erysipelas. He noted that the reactions following successive injections showed a progressive decrease in severity. After several such injections the sera of the rabbits were tested for the presence of protective antibodies. The serum to be tested was mixed with a suspension of living streptococci and injected into the skin of a normal rabbit ; at another site in the same animal another injection was made consisting of a mixture of the same streptococcal suspension and normal serum. The sera from the immunized rabbits had a marked protective action, normal serum had none. The studies of Amoss and Bliss (1927) bring out further points of interest. Like other observers they found that an area of skin which had been involved in an erysipelatous reaction was definitely more resistant to a subsequent injection of the causative streptococcus, and that if the injections were repeated the degree of resistance progressively increased. They noted that the primary lesion in the skin of the rabbit's flank tended to spread ventrally from the site of inoculation in the direction of the lymph flow ; and they found that when the area involved in the primary reaction and the skin in its immediate neighbourhood were tested by subsequent intradermal inoculations the area of increased resistance extended ventrally beyond the area of primary reaction, but not anteriorly, posteriorly or dorsally. At this period no increased resistance could be demonstrated in the skin of the opposite flank. After prolonged immunization the skin at a distance from the site of inoculation might show increased resistance, but this generalized skin immunity was associated with a humoral immunity, evidenced by the appearance of specific antibodies in the blood.

Taking these observations as a whole it would appear that a local immunity to hæmolytic streptococci may exist in the absence of a general immunity, and that, when repeated local injections lead to a general immunizing response, the level of immunity may, for a time at least, be higher in the immediate neighbourhood of the site of inoculation than in the tissues generally. It may be noted that the severe inflammatory reaction associated with an attack of erysipelas is more effective in inducing a local immunity than is the relatively trivial reaction that follows the injection of a killed suspension of streptococci ; and that there is evidence that the tissues become allergic during the immunizing infection.

Although experimental erysipelas provides the best-documented example of a local as opposed to a general immunity, many analogous observations have been recorded in relation to other infections. Cooper (1926), for instance, states that rabbits may be immunized against the injection of virulent pneumococci into the buccal mucosa by repeated injections, into the same tissue, of a killed pneumococcal vaccine, but not by injections of the same vaccine given subcutaneously or intradermally. Other examples of a similar kind will be noted in the succeeding paragraphs.

There are also many experimental observations in relation to virus diseases (see Chapter 55) which suggest that a local immunity plays an important part in determining the reaction of the body as a whole.

We need not doubt that a local immunity exists, in the sense that one area of the tissues is more resistant than another to the introduction into it of a living bacterium or virus. The problem at issue is whether these localized differences in resistance can be accounted for by local variations in the effectiveness of the mechanisms we have considered in previous chapters, or whether some essentially different mechanism is involved.

Is the distribution of a local immunity confined to a particular type of cell or tissue affecting that type of cell or tissue wherever it occurs in the body, or is this distribution determined by the site of inoculation, affecting all cells or tissues in the immediate neighbourhood of that site?

We may particularize our question in regard to the phenomena considered in the preceding section by inquiring whether it is the skin, as such and apart from other tissues, that is rendered resistant by the intracutaneous injection of living hæmolytic streptococci, or whether the effect is limited to the area of the initial erysipelatous reaction, affecting in that area all the cells or tissues involved in the inflammatory process.

The evidence is somewhat conflicting. The observations of Gay and Rhodes appear to favour the view that the skin as such irrespective of its nearness or remoteness to the site of the primary inflammatory reaction is rendered resistant by a localized experimental erysipelas. The findings of most other workers suggest that the distribution of resistance is, in the first instance, confined to the area affected by the erysipelatous reaction, though other areas of skin share in the more general immunity that may be induced by repeated injections of streptococci. It should be noted, as Amoss and Bliss showed, that outside the area of erysipelatous reaction, the skin showing the greatest increase in immunity was that lying in the path of drainage through the underlying lymphatic plexus. The point is of some importance in deciding whether the increased immunity displayed by the skin as a whole results from immunization of the skin as an organ, or is only an especially marked manifestation of a general immunity.

Landsteiner and Chase (1939) record some experiments which are relevant to the issue. They were able to sensitize the entire skin of a guinea-pig to poison ivy by local application of an extract to one area of it. Isolation of the area of application, by removing an annular piece of skin so as to leave an island, did not impair sensitization even though the whole thickness of the skin was thus removed. When the underlying lymphatic plexus, and consequently the only pathway for the ready absorption of the extract into the body as a whole was severed, general sensitization did not follow application of the extract.

The question posed leads naturally to the one that follows it, and data relevant to its solution will be considered under this and other heads.

Does the local immunity as such, and apart from an associated humoral immunity, confer an increased resistance on the body as a whole?

It will be convenient to commence our discussion of this question by setting out, in their baldest terms, the views that have been put forward by Besredka (1919, 1920, 1921).

He notes that many, if not all, pathogenic bacteria show a marked tendency to specific localization in particular tissues of the body. Thus the typhoid, paratyphoid and dysentery bacilli cause intestinal infection, while the anthrax bacillus commonly causes infection of the skin. He would, however, carry this argument much further than those who regard such frequency distributions as the expression of a modal type of infection, determined by a variety of interacting factors and often departed from in particular instances. He believes, for instance, that the localization is in no way dependent on the route by which the bacteria enter the body. By whatever path typhoid, paratyphoid or dysentery bacilli gain access to the tissues they pass to the intestines, and there produce their distinctive lesions. Similarly, for a fatal anthrax infection to result, the anthrax bacillus, however introduced, must reach the skin.

As a logical corollary, a naturally immune or an actively immunized animal owes its increased resistance to the local immunity possessed by the particular tissues which are, in susceptible animals, specifically liable to attack. If these susceptible tissues are rendered immune then the whole animal is immune, because the specific localization which is an essential feature of bacterial infection can no longer occur. Thus, in the last analysis, general immunity is simply the expression of effective local immunity. The various antigen-antibody reactions that have been observed are, in reality, of altogether minor importance.

These conclusions are clearly revolutionary and provocative ; and like all provocative conclusions based on experimental study they have acted as a stimulus to further research. Taken as they stand, it seems hardly necessary to do more than confront them with the evidence set out in the preceding chapters in order to demonstrate that they cannot be accepted as an adequate picture of the facts. Whether a localized immunity in Besredka's sense plays any part in resistance to bacterial infection is another matter.

Taking the case of experimental typhoid, paratyphoid or dysentery infection in rabbits, Besredka lays emphasis on the point that these animals can be effectively immunized by feeding with dead or living cultures. When dead bacterial cells are used for immunization, it is sometimes necessary to administer in addition a small dose of bile, which causes minimal lesions of the mucous membrane. The fact that an increased resistance can be induced in this way does not, however, afford any evidence in favour of the conception of a specific induced immunity of the intestinal mucosa. We have seen (p. 1117) that the administration of dead or living bacteria by the mouth is often followed by the passage of bacterial antigens from the intestines to the tissues and this, in its turn, by the usual antibody-forming response. The argument on which Besredka lays most stress in this particular instance is the following. He states that when dysentery bacilli are administered to rabbits by the mouth agglutinins may appear in the blood after the first administration, but they soon disappear, and do not reappear after any subsequent administration. He records analogous observations in the case of rabbits immunized by the oral administration of typhoid bacilli after preliminary treatment with bile ; and, in both cases, he interprets the early disappearance of agglutinins, their failure to reappear after subsequent administration of bacteria *per os*, and the increasing resistance to infection by any route, to the establishment of a local immunity of the intestinal mucosa, which presents an impenetrable barrier to the passage of bacteria from the intestines to the tissues, and at the same time

prevents the essential selective localization of the bacilli should they gain access to the tissues by some other route. The few experiments recorded by Besredka seem quite inadequate to form a basis for such an important and far-reaching conclusion; and, as Otten and Kirschner (1927) have pointed out, the crucial observation of the disappearance of antibodies from the blood during a series of repeated administrations of vaccine *per os* finds no adequate confirmation in the results obtained by other workers.

Turning to the case of anthrax, controversy has centred round Besredka's contention that the skin alone is susceptible to this infection. Balteano (1922) states that he has confirmed Besredka's findings. Plotz (1924) carried out a series of experiments in which cultures of *B. anthracis* were enclosed in thin-walled glass bottles and introduced into the subcutaneous tissue of rabbits. The wounds were allowed to heal and at various periods thereafter the bulbs were broken *in situ* and the contained culture was allowed to escape into the surrounding tissues. The majority of such animals survived, and Plotz concludes that the rabbit can resist a large subcutaneous inoculation of *B. anthracis*, provided that the bacilli do not come into contact with any wound of the skin.

Other investigators have, however, recorded quite different results. Sobernheim and Murata (1924) estimated the minimal lethal dose of a culture of *B. anthracis* when administered by different routes. They found that about 1/10,000 of a loopful would produce death when introduced intraperitoneally or intravenously, about 1/100,000 of a loopful when introduced subcutaneously or intracutaneously and about 1/1,000,000 of a loopful when injected intramuscularly.

It is obviously difficult to avoid infecting the skin when making injections into any subjacent tissue, and this objection has been urged against those who have recorded successful infection by some route other than the intracutaneous; but Besredka's assumption can hardly be reconciled with the observation that a *smaller* dose of bacilli is required to produce a fatal infection when the inoculation is made into the muscles than when it is made directly into the skin. Similarly, Basset (1925) was unable to demonstrate any superiority of the intracutaneous as compared with the subcutaneous or intramuscular route. Muller (1925) has recorded results which are directly opposed to those obtained by Plotz. He states that, several years before his paper was published, he had inoculated a pigeon's egg with anthrax bacilli, sealed the opening, and introduced the egg into the peritoneal cavity of a rabbit. Five weeks later this animal died from anthrax. Unable to reconcile this result with Besredka's views he carried out further experiments of the same type, but with a slightly different technique. Finding that anthrax bacilli would grow slowly through the pores of an L_1 candle, he placed cultures of the organism in such candles, sealed them carefully, and introduced them into the peritoneal cavities of nine rabbits. Seven of these animals died after intervals varying from 6 to 51 days. This long incubation period would appear to preclude an infection of the skin occurring at the time of the introduction of the candles. Burke and Barnes (1931) have utilized the bactericidal action of gentian violet in an attempt to produce an initial subcutaneous infection with *B. anthracis* unassociated with any primary infection of the skin. A guinea-pig was injected with a young culture of *B. anthracis* by introducing the needle through the skin of the abdominal wall in one flank, and then passing it subcutaneously across the abdomen to the other flank, where the inoculum was deposited. The point of the needle was then withdrawn to just beneath the skin puncture, the syringe barrel was detached, another barrel containing a 1 per cent. solution of gentian violet was attached, and the dye was introduced into the puncture as the needle was withdrawn. The guinea-pig died in 56 to 72 hours. The characteristic gelatinous infiltration occurred at the point where the inoculum had been deposited, not at the point where the needle had been inserted. Cultures from the dye-stained area about the site of the skin puncture remained sterile. It seems fair to conclude that Besredka's contention with regard to the unique susceptibility of the skin to anthrax has not been proved. Besredka and his colleagues (Besredka 1924*a*, *b*, Besredka and Urbain 1924) have also attempted to immunize the skin against other bacteria. They applied filtrates from broth cultures of staphylococci or streptococci to

the shaved skin of rabbits, and tested the resistance of these areas of skin to subsequent infection with the homologous organisms. From their results they conclude that this procedure confers a high degree of local immunity. In later reports they, and others, have recorded valuable curative properties in these filtered cultures—the so-called "anti-virus" preparations—but these observations do not bear directly on the problem at issue, and need not be further considered.

We need not doubt that various procedures of this kind may raise the resistance of local areas of skin to subsequent infection; but it by no means follows that this is associated with an increase in the resistance of the body as a whole.

Thus, Hach, Borodaj and Melnyk (1928) state that staphylococci, after intravenous inoculation into rabbits, tend first (3–3½ hours) to accumulate in the spleen, few remaining in the blood and few being present in the skin. As the infection progresses towards its rapidly fatal issue the distribution changes; the number of cocci in the spleen rapidly diminish, the number present in the skin show an enormous increase. Multiple intradermal inoculations of a staphylococcal filtrate, preceding the intravenous injection, prevented this rapid accumulation of staphylococci in the skin (Hach and Melnyk 1928); but there was no effective immunity, the rabbits dying of typical acute staphylococcal infection.

Is local immunity specific or non-specific?

We may now return to the more general question of the nature of the mechanisms that determine those types of local immunity that have been shown to exist, and inquire particularly whether they are in the main specific or non-specific.

Cobbett and Melsome (1898) found that a local non-specific inflammatory reaction, such as that following the injection of mustard oil, would effectively protect the skin of a rabbit's ear against subsequent attempts to produce experimental erysipelas.

Amoss and Bliss (1927) noted that the localized resistance following an erysipelatous lesion was not sharply specific. It was effective against strains of hæmolytic streptococci antigenically dissimilar from the strain producing the initial lesion, and to a less extent against *Staphylococcus aureus*. Rivers and Tillett (1925), studying the properties of the serum derived from the rabbits in which they had produced a localized antistreptococcal immunity, found that such immune serum injected into the skin 24 to 48 hours before the injection of living streptococci into the same site rendered this site relatively refractory to infection. Similar results were, however, obtained by the injection of normal serum, or of ordinary nutrient broth, though the protection in this case was less effective and quite non-specific. Mallory and Marble (1925) prepared filtrates from cultures of staphylococci and streptococci. With these they infiltrated localized areas in the skin of a rabbit, and found that such treatment conferred a strictly localized but non-specific immunity lasting for 5–6 weeks. This increased resistance was, however, little if any greater than that conferred by the infiltration of the skin with sterile broth. Analogous results have been recorded by Miller (1927), Freedlander and Toomey (1928), Hanger (1930), Toomey and Freedlander (1931), and Bridré and Bardach (1936).

Freedlander and Toomey carried out a detailed histological study of the reactions induced in the cutaneous tissues by the application of compresses of sterile broth, and of the reactions that followed the subsequent injection of *Staphylococcus aureus* into these treated areas. They found that the application of the broth compresses to the abdominal wall of the guinea-pig, for a period of 48 hours, produced a localized œdema, a marked proliferation of histiocytes and a moderate exudation of polymorphonuclear and small mononuclear cells. The cellular response to the subsequent injection of *Staphylococcus aureus* differed widely in treated and untreated animals. In the broth-prepared animals there was an increase in the histiocytes and fibroblasts with a dense exudation of poly-

morphonuclear cells, which showed little tendency to degenerate. The histiocytes phagocytosed the staphylococci at an early stage of the reaction, while the proliferating fibroblasts tended to wall off the lesion. In the control animals the œdema following the bacterial infection was more marked, there was little proliferation of histiocytes or fibroblasts, and the polymorphonuclear cells, which collected in considerable numbers during the earlier stages of the reaction, showed a marked tendency to undergo degeneration at a later period. The reaction was in general more severe and destructive and far less localized.

It would seem justifiable to conclude that there is an important non-specific element in the local immunity that follows the injection into the skin of various reagents, or its treatment with compresses, etc., and that this non-specific increase in resistance is determined in large part by the mobilization of various phagocytic cells, and perhaps by changes in the local capillaries and lymphatics.

Non-specific immunity of this type is by no means limited to the skin.

Pfeiffer and Issaeff (1894) showed that the injection of such materials as broth, peptone solutions or urine into the peritoneum of the guinea-pig would so alter the local conditions that the animal became resistant to the intraperitoneal injection of living cholera vibrios in doses fatal to untreated control animals. It is not justifiable to regard this particular non-specific immunizing reaction as local, in the same sense as the cutaneous reactions considered above, since material injected into the peritoneum is rapidly transferred to the blood stream, and a generalized non-specific response of the type discussed in Chapter 52 may well be concerned, in addition to any possible local effect.

Gay and Morrison (1923) injected various substances intraperitoneally into rabbits, and injected living streptococci 24 hours later. They found that certain substances, such as meat-extract broth, afforded marked protection, while others, such as aleuronat, did not. They noted that the substances which conferred protection were those that produced exudates in which macrophages were particularly numerous, while those that produced exudates containing numerous polymorphonuclear cells but few macrophages were far less effective.

Oerskov and Kauffmann (1936) and Oerskov (1940) record examples in mice of an intraperitoneal immunity to Vi forms of *Salm. typhi* and to *Sh. shigæ* that could be induced non-specifically by the injection of living or dead preparations of bacteria having no antigenic relationship to the infecting strain. Philipson (1937) has made an extensive study of the immunity to *Sh. shigæ* induced in mice by vaccines of *Salm. paratyphi B*. He found that a relatively high degree of non-specific immunity to intraperitoneal *Sh. shigæ* was demonstrable 8 hours after an intraperitoneal dose of vaccine, and lasted 3–9 days. When two doses of vaccine were given at a 9-days' interval, the immunity was demonstrable 2 hours after the second dose, and lasted up to 21 days. Thus the period of induction of the immunity was shortened, and its duration lengthened, by the re-vaccination. An intraperitoneal immunity of this degree, demonstrable 2 hours after the second dose of vaccine, could not be induced by intravenous vaccination and re-vaccination, nor by intravenous vaccination and intraperitoneal re-vaccination. Some immunity, however, followed intraperitoneal vaccination and intravenous re-vaccination, indicating that the stimulating effect of re-vaccination could be elicited in the peritoneum by blood-borne vaccine. Though the immunity was clearly non-specific, the stimulating effect of re-vaccination was in some way dependent on specific factors, for vaccination by one species of bacterium, and re-vaccination by an antigenically unrelated bacterium, was not followed by any significant increase in immunity.

Walsh and Cannon (1936) immunized rabbits against intranasal infection of the lungs with Type I pneumococci, by five or more daily instillations of formol-killed Type I pneumococci. The immunity was specific, though it appeared before antibodies were demonstrable in the blood of the animals. Cannon and Walsh (1937) recorded experiments which point to the induction of a local, perhaps specific, immunity in the lung by

this procedure—an immunity apparently dependent on an increased resistance to the passage of the cocci from the alveoli into the tissues (see also Exchaquet 1936). Similar results were obtained by North and Anderson (1942) who found that intranasal *H. pertussis* vaccines were more effective than intraperitoneal vaccines for immunizing against intranasal *H. pertussis*. They concluded, however, that the superiority of the intranasal route was due to non-specific immunity, since the antibody response to vaccination by either route was similar. Intranasal vaccines made of organisms more or less related to *H. pertussis*—*H. influenzæ*, *H. parapertussis* and *H. bronchisepticus*—were also effective. No immunity resulted from instillation of staphylococci or pneumococci, but a *Bact. coli* vaccine was highly effective. The efficacy of the *Bact. coli* appeared to depend on its capacity to induce a histological reaction in the lung similar to that induced by *H. pertussis*. Serologically speaking, the effect was non-specific. It is salutary to reflect that, had the test with *Bact. coli* been omitted, the evidence would have been of the kind we are accustomed to regard as a reasonable indication of the specificity of a particular immunizing effect.

It should be noted that the local changes associated with inflammation are not always protective. They may even increase susceptibility. Thus Olitsky and Schlesinger (1941) enhanced the infectivity of herpes virus for mice by first inducing œdema at the inoculation site with hypertonic salt solutions. Full inflammation induced by turpentine, on the other hand, was protective.

It is clear, then, that there is an element, in some cases a strong element, of non-specificity in local immunity. Its existence by no means excludes the possibility that specific factors are also operative. On this point the evidence is scanty, though, as we have seen in Chapter 50, there are indications that specific antibody formation occurs, not only in local lymph nodes, but in the skin also. The few experiments recorded on local antibody formation in the skin suggest that a conspicuous local proliferation of cells is a necessary preliminary to the formation of detectable antibody. It is possible, however, that an immunologically effective local response might take place in the absence of a gross proliferative lesion, and contribute to a specific local immunity.

Is local immunity necessarily associated with a cellular or tissue immunity in the strict sense?

There is, as has been pointed out above, no necessary correlation between local immunity and cellular immunity in the sense here implied—an immunity which belongs to the cell as such apart from its immediate environment and, in particular, apart from any antibodies which may be present in the tissue fluids in its immediate neighbourhood. A cellular immunity might well be widespread in its distribution, and effects. A local immunity may be due to a variety of factors other than an acquired resistance of particular cells.

None of the observations outlined above necessitates the assumption that a cellular immunity is involved; but all of them are quite compatible with its existence.

In this relation we may recall certain facts in regard to the formation and distribution of antibodies, and the phenomenon of anaphylaxis and hypersensitiveness. The serum antibodies, wherever they are produced, are rapidly distributed throughout the tissues, and are in part fixed by various tissue cells. We know almost nothing of the mechanism of this fixation, or of how the antibodies are distributed among the tissue cells. We do know, however, that a cell that has taken up its quota of a given antibody reacts specifically to the presence of the

corresponding antigen; and this mechanism would seem to be involved in those allergic reactions that are associated with infection and immunity. A "cellular immunity" of this type, and conditioned in this way, almost certainly occurs; though we have, at the moment, no knowledge of what part it plays in the mechanisms of immunity in general.

SUMMARY

The evidence available appears to justify the following conclusions.

(1) By the injection of various materials into the tissues, and by certain analogous procedures, it is possible to induce an immunity which is confined to the neighbourhood of the treated area, and is not shared by the body as a whole.

(2) This immunity appears to be distributed in accordance with the area involved in the original inflammatory reaction, not in accordance with the distribution throughout the affected part or throughout the body generally of one particular type of cell. There is good evidence of a localized immunity affecting an *area* of skin, or a particular serous sac. There is no adequate evidence of an immunity affecting the skin as a whole, or the intestinal mucosa as a whole, or serous surfaces as a whole, except as the expression of a general immunity.

(3) It follows that we cannot accept the conclusion that a localized immunity of the latter type is an essential factor in a general immunity. Even had an induced skin immunity, or mucous membrane immunity, been shown to exist, our knowledge of the general defence mechanisms of the body would prevent us from regarding such a local increase in resistance as the essential factor in antibacterial immunity.

(4) All the evidence suggests that non-specific factors are of primary importance in those instances of local immunity that have been submitted to experimental study. It would appear to be the initial inflammatory reaction as such, and the cellular changes which persist for some time after it has subsided, that determine the relative resistance of the treated area to subsequent experimental infections. In particular it would seem that any treatment which induces a local mobilization and concentration of histiocytes will confer on the treated area an increased resistance, which will last as long as the local cellular changes persist. There is some evidence that with the decline of the cellular change, the treated area remains for some time more responsive than normal to non-specific immunization.

(5) When a localized area is repeatedly treated with a particular bacterium, a general immunity is often superimposed on the local immunity. There is nothing in the evidence at present available to suggest that such general immunity, in so far as it is specific, differs essentially from the specific antibacterial immunity that we have considered in earlier chapters.

(6) The problem of the existence of a cellular, as opposed to a humoral, immunity is distinct from that of the existence of a local, as opposed to a general, immunity. There is nothing that compels us to assume the existence of a cellular immunity; but it would accord well with several experimental findings. If such a mechanism plays an essential part in immunity, it seems quite possible that it is conditioned by the fixation by various tissue cells of specific antibodies, and is hence only a humoral immunity at one remove.

CHAPTER 54

THE INFLUENCE OF DIET, FATIGUE, CHANGES IN TEMPERATURE AND HUMIDITY, CHEMICAL AND CHEMOTHERAPEUTIC AGENTS AND OTHER FACTORS ON GENERAL OR LOCAL IMMUNITY

The Influence of Diet on Immunity

It will be convenient to discuss first the effects produced by deficiency or excess of the accessory food factors, or *vitamins*.

Many of the reports of the action of vitamins on the immune reactions in man and animals are contradictory, especially those of earlier workers in the field. Doubtless some of the contradictions are due to lack of knowledge of what constitutes a deficiency or an excess of a particular dietary factor, and to variations in the conditions of the experiments; but one of the most likely sources of error is the complexity of the vitamin preparations used. It is perhaps possible to say with conviction that a certain vitamin is in excess or deficient in a given diet, but the presence or absence of active amounts of other essential food substances is often problematical. In a few cases, as with Vitamin C, the difficulty may be overcome by comparing the effect of the synthetic vitamin with that of a preparation from natural sources; for though neither can with certainty be declared free of other vitamins, it is unlikely that the same contaminants will be present in both. In other cases we must rely on the chemical and biological evidence that the vitamin under test is a single substance free from contamination. The interpretation of vitamin work is often complicated by ignorance of the nutritional state of the animals under test. There may be, for example, a large difference between the optimal vitamin content of the tissues, and the level at which signs of vitamin deficiency appear; and of two apparently normal animals, one may have ample reserves of a vitamin, while the other will become clearly abnormal after only a short period of dietary deficiency. In these circumstances, discrepant results of experimental variations in vitamin intake are to be expected unless there is careful control of all the significant nutritional variables.

Another source of error has been demonstrated, particularly with regard to the vitamins of the B complex: namely, the contribution of the microbial flora of the gut to the nutrition of the animal under test. The synthesis and destruction of vitamins by intestinal bacteria is discussed in Chapter 90. We may note here that the intestinal flora may vary widely in its vitamin production, and that the bacterial vitamins may supplement, or even replace, the dietary supply of an essential vitamin. We need not labour the complications introduced into nutritional experiments by the normal bacterial flora of the intestine. To take one instance, it will be evident that the addition or omission of a non-vitamin dietary con-

stituent, by inducing a gross variation in the intestinal flora, may profoundly alter a vitamin balance that is largely maintained by microbial activity in the intestinal canal; and the consequences of the alteration may be attributed directly to the change in diet.

Variations in the Intake of Vitamin A.—In 1909 Knapp described a curious condition of the eyes developing in rats fed on a deficient diet. This condition (xerophthalmia) is characterized by a thickening and drying of the superficial epithelial covering of the eye, patchy in distribution, and associated in its later stages with a subacute bacterial infection of the underlying tissues. Knapp did not ascribe these lesions to any specific dietary deficiency; but we know now that the essential factor in its causation is lack of the fat-soluble Vitamin A, and Knapp's protocols show that the diet he employed was, in fact, deficient in this constituent. Similar lesions have since been described by many other observers, not only in the rat but in other animals, such as the rabbit (Nelson and Lamb 1920, Boock and Trevan 1922) and the dog (Steenbock, Nelson and Hart 1921). Particularly interesting is the account of Bloch (1921, 1928) of the occurrence of numerous cases of xerophthalmia in Danish children during the 1914–18 war, when the supply of animal fats to the general population, and in particular to the dwellers in large towns, was greatly restricted. The increased susceptibility to bacterial infection that results from Vitamin A deficiency is, however, by no means limited to the superficial tissues of the eye. In describing the condition of the children in Copenhagen Bloch remarks: "It is absolutely characteristic of these dystrophic children how little they are able to withstand infections, and how quickly they die of serious intercurrent fever." The most important killing disease that developed among them was broncho-pneumonia. Blegvad (1923) records the following incidence of serious complicating infections among the cases of xerophthalmia—broncho-pneumonia 63, bronchitis 45, pyuria 42, otitis media 30. These clinical observations are in entire accord with the results obtained in dietary experiments on animals.

The liability of rats fed on a diet deficient in Vitamin A to develop intercurrent infections, such as glandular abscesses, suppurative arthritis, suppurative otitis, pyelonephritis and broncho-pneumonia, has been noted by many observers (Drummond 1919, Hess *et al.* 1921, Cramer 1923, 1924, 1927, Gross 1924, Wolbach and Howe 1925, Green and Mellanby 1928, 1930, Gudjónsson 1930). The more precise knowledge that has accrued within recent years in regard to the chemical nature of certain of the vitamins has made it possible to demonstrate clearly that the fat-soluble vitamin concerned is A, not D (see Goldblatt and Benischek 1927, Green and Mellanby 1928); and to establish, in this respect as in others, the functional similarity of Vitamin A and carotene (Green and Mellanby 1930).

These observations on the increased frequency of spontaneous infections have been confirmed and extended by testing the resistance of animals kept on an A-deficient diet to experimental infection (Werkman 1923*b*, Hotta 1928, Reiter 1929, Lassen 1930, 1931, 1932, McClung and Winters 1932, Greene 1933, Robertson 1934). Lassen's studies are of particular interest, since the course of infection in the avitaminotic and control animals was followed in considerable detail. Rats were reared on a diet lacking Vitamin A, and were then infected, together with control rats of the same age fed on a complete diet, by administering living cultures of *Salm. typhi-murium* by the mouth, or by subcutaneous or intravenous injections. The avitaminotic rats showed a significantly lower resistance than the normal

controls. In the experiments in which the bacilli were administered by the mouth, the course of the infection was studied by the technique employed by Ørskov, Jensen and Kobayashi (see p. 1046). The rats were killed at various intervals after infection and cultures taken from the intestines, Peyer's patches, mesenteric glands, liver, spleen, lungs and heart's blood. In the normal rats the infection tended to be limited to the Peyer's patches and mesenteric glands, with some extension to the liver and spleen. In the avitaminotic rats it tended to become generalized, and to produce a fatal bacteræmic infection. In the few experiments in which the bacilli were injected intravenously, the avitaminotic rats showed the same initial clearing of the blood stream as did the normal controls, but in the former this initial clearance was followed by a secondary bacteræmia and a fatal generalization of infection.

By adding irradiated ergosterol to the Vitamin A-deficient diet and noting that this procedure did not prevent the fall in resistance to experimental infection, Lassen (1931) was able to show—as Green and Mellanby had done in the case of spontaneous infections—that the effect of removing all fat-soluble vitamins from the diet was due to the absence of Vitamin A.

It may be noted, and this is a point of some importance, that Lassen found it necessary to induce a pronounced degree of avitaminosis before he could demonstrate a well-marked break in resistance. He states that a slight decrease in resistance occurs after 2 to 3½ weeks on a Vitamin A-free diet, at a time when the animal shows no clinical evidence of avitaminosis, but that the clear and significant fall in resistance sets in suddenly at a later stage, coincidentally with the appearance of xerophthalmia.

The mechanism that underlies the decreased resistance of animals deprived of Vitamin A is as yet far from clear. Cramer (1923, 1924) has described atrophic changes in the intestinal mucosa of avitaminotic rats, and believes that the lesions facilitate the passage of bacteria from the intestines to the tissues. Wolbach and Howe (1925) record striking changes in the surface epithelium in certain situations, though they locate these lesions in the lining membranes of the nares, trachea, bronchi and genito-urinary tract, rather than in the intestine. These observations would suggest that the increased susceptibility to infection associated with A-avitaminosis may be due, in part at least, to a failure of the first-line defence mechanisms discussed in Chapter 45; but such a view is difficult to reconcile with other evidence on record. Thus Lassen (1931) found no difference in the rate at which bacteria passed from the intestine to the mesenteric glands *via* the Peyer's patches and lymph follicles, as between normal and avitaminotic rats. It was in the subsequent course of events—the fatal generalization of infection as opposed to its successful localization—that the avitaminotic animals displayed their lack of effective resistance. Moreover (Hotta 1928, Reiter 1929, Lassen 1930, 1931, 1932) such animals are more susceptible than normal controls to the subcutaneous, intraperitoneal and intravenous injection of bacteria—in which the first line of defence is artificially ruptured—as well as to the administration of pathogenic bacteria by the mouth (see also Stryker and Janota 1941). On the other hand, Sternberg and Pillsburg (1937) were unable to detect any lowering of the resistance of rats to intradermal infections with staphylococci and streptococci, as the result of Vitamin A deficiency.

It would seem, therefore, that there must be some defect in the defence mechanisms of the tissues—in the efficient functioning of the reticulo-endothelial system itself, or in the conditioning or accessory action of the humoral antibodies—but of the nature of that defect we have as yet no knowledge. It may be noted in this connection that most workers have failed to find any satisfactory evidence that deprivation of Vitamin A—or indeed of any other vitamin—reduces the efficiency of antibody production in response to a

specific stimulus (see Zilva 1919, Werkman 1923*a*, *b*, Werkman, Nelson and Fulmer 1924, Cramer and Kingsbury 1924, Simola and Brunius 1933), though Greene (1933) records an apparently significant decrease in the ability of A-avitaminotic rabbits to produce hæmolysins for sheep's red cells and Jusatz (1936*a*) a depression in rabbits both of the bactericidal power of the blood and of the formation of precipitins for horse serum after prolonged feeding on a diet free from vitamins A and D. Lassen (1931, 1932) notes that the sharp difference in resistance between normal and avitaminotic rats cannot be demonstrated when both groups have been previously immunized by the injection of a heat-killed vaccine, which indicates that the antibody-producing mechanism is still functioning with effect. Boynton and Bradford (1931) tested the resistance of rats to artificial infection with a bacillus of the Friedländer group, and found that it was lowered by Vitamin A deficiency even before signs of avitaminosis had developed.

With progressive deficiency Gellhorn and Dunn (1937) observed a progressive fall in the phagocytic index of rat-blood, which was reversed when Vitamin A was restored to the diet. The association of this effect with deficiency is dubious, since the deficient rats suffered from spontaneously acquired infection, which may itself have affected the phagocytic index. The significance of lysozyme in defence against infection is not clear (see Chapter 45) but it may be noted that in deficient rabbits Sullivan and Manville (1937) found a retention of lysozyme in the intestinal tissues, and a diminution in the mucous secretions.

Observations have been recorded suggesting that the deprivation of Vitamin A renders animals more susceptible to the injection of bacterial toxins, as well as to the invasive action of living bacterial cells (Werkman, Baldwin and Nelson 1924, Schubert 1928). Torrance (1936), however, in a careful study of the Vitamin A content of the liver in guinea-pigs, found no association between vitamin level and susceptibility to diphtheria or tetanus toxin (see also Chalier and Jeune 1938).

It is possible that the whole effect of Vitamin A deficiency is indirect. Kligler, Guggenheim and Henig (1945) found, in accordance with a number of other observers, that resistance of rats and mice to infection—in their case with *Salm. typhi-murium*—was not significantly lowered by a partial Vitamin A deficiency, but only by a complete avitaminosis. Avitaminosis was, however, invariably associated with declining weight in the experimental animals. In other words, the decline in resistance appeared to be due to starvation, a conjecture supported by the fact that rats whose food intake was restricted to the same amount as that eaten by avitaminotic rats, while the Vitamin A intake was normal, were as susceptible as the avitaminotic animals to the salmonella infection.

We have been concerned so far with a comparison between animals fed on a normal diet and those deprived of Vitamin A. The former have clearly an advantage; but it is by no means a necessary corollary that an excess of Vitamin A will raise the resistance above normal level.

There are as yet no adequate experimental or field data on which a sound opinion on this further problem can be based. It is intrinsically a difficult one, since it really resolves itself into comparisons of resistance over a wide range of different levels of Vitamin A intake. The amount that is required for normal growth may fall short—even if not far short—of the amount required for optimal resistance.

Among other experiments that have a bearing on this point are those of Webster and Pritchett (1924) on the influence of diet on susceptibility to experimental infection with *Salm. typhi-murium*. They compared the resistance of mice fed on the ordinary diet of the Rockefeller Institute—a daily ration of bread, soaked in fresh, pasteurized, Grade B milk, supplemented by two weekly feedings of an oatmeal and buckwheat mixture and one weekly feeding of dry biscuit—with that of mice fed on a modified McCollum diet containing wheat flour, casein, milk powder, butter fat and salts. Mice kept on these diets were tested

in groups of 10–36 animals, by the injection through a stomach tube of 2–5 million *Salm. typhi-murium*. The results indicated that the mice fed on the McCollum diet were significantly more resistant than those fed on the ordinary laboratory diet. Pritchett (1927) records a more numerous series of experiments along similar lines, in which an attempt was made to assess the influence of the different constituents of the McCollum diet. The increased resistance of the mice fed on this diet was in general confirmed; but the effects produced by varying its constitution were not easy to interpret. For instance, the entire withdrawal of butter fat—the only source of Vitamin A—left the mice more resistant than the mice on the ordinary laboratory diet, though less resistant than those on the full McCollum diet. On the other hand the addition of butter fat to the normal laboratory diet was followed, in four of seven trials, by a lowering of mortality as compared with the control group; and a similar result was obtained by the addition of cod-liver oil. In a later series of experiments on the effect of diet on the epidemic spread of mouse typhoid Webster (1930) records results from which he concludes that the substitution of the McCollum diet for the ordinary laboratory diet increases the resistance of mice to contact infection.

In another series of observations along similar lines (Topley, Greenwood and Wilson 1931) different results were obtained. Mice fed on a basal diet of whole-wheat flour, casein, butter and a salt mixture showed no advantage over mice fed on a diet of whole oats, milk and water as regards their ability to resist infection during an experimental epidemic of *Salm. typhi-murium* infection. The addition of an excess of fat, butter or lard, or of a Vitamin-A concentrate to this diet appeared to react unfavourably on the mice at risk. The unfavourable action of these artificial diets was not manifest when the mice were infected by intraperitoneal inoculation. Under these conditions there was a suggestion that the mice fed on the usual laboratory diet of oats, milk and water were slightly less resistant than the other groups, but the differences observed were quite insignificant. In order to avoid the possible complication introduced by the excess of fat in the vitamin-rich diets, other experimental epidemics were initiated in which the vitamin content of the normal laboratory diet was increased by the addition of a ration of carrot or of cabbage. The mice receiving carrots appeared to be at a disadvantage as compared with those on the normal diet; the addition of cabbage produced no significant change in mortality. It may be noted that Lassen (1931) records that a considerable excess of shark-liver oil in the diet caused a slight decrease in the resistance of rats to experimental paratyphoid infection.

These experiments are considered here because some of them at least have a bearing on the effect of an excess of Vitamin A over the amount required to maintain growth and apparent well-being; but it would in truth be unwise to lay much stress on their significance, since it is clear that the diets employed varied in many ways besides their differences in Vitamin A content. It does, however, seem fair to conclude that no adequate experimental evidence has yet been produced that an excess of Vitamin A over the level required to prevent all overt signs of avitaminosis induces an increased resistance to bacterial infection.

Little evidence is available with regard to the effect of increasing the amount of Vitamin A supplied to human subjects. The collection of such evidence clearly demands special conditions. The infections associated with child-birth afford opportunities for such a trial, and are of particular interest because of the obvious possibility that pregnancy may make a large call on the vitamin reserves. Mellanby, Green and their colleagues (Green *et al.* 1931) record a trial in which 275 women received a Vitamin-A concentrate by mouth during the last month of pregnancy, the incidence of varying degrees of morbidity among this group during the puerperium being compared with the corresponding figures for a control group of 275 women not so treated. In every comparison the treated group fared better than the untreated. Thus 19·2 per cent. of the treated women suffered from pyrexia,

as against 30·9 per cent. of the untreated; while for severe pyrexia the figures were 1·5 per cent. and 3·6 per cent. respectively. The evidence so far as it goes clearly suggests that the administration of Vitamin A in large amounts has some prophylactic value against the risk of puerperal infection.

There is no obvious reason for supposing that the administration of excess of Vitamin A would exert a beneficial effect on an already established infection; and most of the scanty evidence available is in accord with the *a priori* probabilities. Mellanby and Green (1929) reported a few cases from which they concluded that a therapeutic effect was exerted in puerperal fever; but the studies of Thomas (1931) on a far larger series of puerperal cases showed no benefit, either in mild or serious infections. Orenstein (1932) failed to find any evidence that the administration of a highly potent preparation of Vitamin A has a beneficial effect on cases of pneumonia occurring among the native workers on the Rand mines. Over a 1-year period alternate cases were treated with this preparation. Of 375 treated cases 10·13 per cent. died; of 389 untreated cases 10·28 per cent. died.

Variations in the Intake of Vitamin B.—The Vitamin B complex includes defined vitamins like Vitamin B_1, or thiamin, which is relatively heat-labile, and the heat-stable B_2 complex, which includes nicotinic acid, riboflavin, pyridoxin, pantothenic acid, biotin, and other substances. It would appear both from clinical records and from experimental studies that a deficiency in the intake of Vitamin B_1—the antineuritic vitamin—has no effect on resistance to infection at all comparable to that produced by a lack of Vitamin A. In the earlier records there are suggestions that B-avitaminosis is associated with a minor increase in susceptibility to infection, but the evidence is of very doubtful significance (see Werkman 1923*a*, *b*, Werkman, Baldwin and Nelson 1924, Lassen 1929, 1931, 1932, Robertson 1934).

The effect of a prolonged suboptimal intake of the vitamin B complex was studied in rats by Drummond and others (1938). The deficient rats had feebler reproductive powers, were shorter-lived, and post mortem showed a significantly higher incidence of gastro-intestinal lesions, than those in a control group on a full diet. Nevertheless, they suffered from no epidemics, and the incidence of bronchiectasis, the only infective disease to which the rats were prone, and of sporadic pneumonia and abscesses, was the same in deficient and control groups. Rose and Rose (1936) compared the course of artificial *Staph. aureus* bacteræmia in 8 normal and 8 B_1-deficient dogs. The deficient dogs lost weight more rapidly, and suffered a more prolonged bacteræmia, but there was no significant difference in the recovery rates in the two groups. They found no depression of resistance to *Cl. welchii* toxin in deficient dogs (Rose, Rose and Kolmer 1936). Janota and Dack (1939) record that the anæmia, leucopænia, gingivitis, œdema and diarrhœa which follow B_2 deficiency in monkeys, is associated with the spontaneous appearance of *Sh. flexneri* in the stools. Rats fed on B-deficient (Lamb 1935) or thiamin-deficient diets (Badger, Masunanga and Wolf 1940) exhibit a decreased resistance to rat leprosy. Woolley and Sebrell (1942) maintained mice on thiamin- and riboflavin-deficient diets for 2–3 weeks, and found a diminished resistance to intranasal infection with Type I pneumococci. Robinson and Siegel (1944), using comparatively small numbers of animals, studied the effect of restricted B vitamin intake on rats injected intratracheally with a mixture of mucin and Type I pneumococci. Compared with rats on a defined, "synthetic" diet containing adequate amounts of known B vitamins, neither riboflavin- nor pantothenic acid-deficient rats were less resistant; thiamin deficiency, and to a less significant degree, pyridoxin deficiency, lowered the resistance. Rats on a "normal" stock diet, it should be noted, were as susceptible as thiamin-deficient rats.

Among virus diseases the effect of deficiency varies. Cowdry, Lucas and Neff (1935) found no diminution of resistance to injection with herpes virus in B_1- and B_2-deficient

rats. Kuczynski (1937) increased the survival rate of normal mice injected with yellow fever virus from about 20 per cent. to about 75 per cent. by increasing the dietary thiamin. It is doubtful whether these effects are specific. For example, Sabin (1941) has shown that though thiamin or B-complex deficiency delays the normal acquisition by mice of an adult resistance to encephalitis induced by the virus of vesicular stomatitis, a similar delay occurs when food is restricted, and the dietary B vitamins are adequate. In this connection we may note that Cottingham and Mills (1943) found a lowered phagocytic activity in the blood of rats which were deficient in thiamin, riboflavin, pyridoxin, pantothenic acid or Vitamin C only when the deficiency in each case was sufficient to retard the growth of the animals.

Experimental poliomyelitis provides an example of a disease in which vitamin deficiency is apparently beneficial. Compared with normal mice, the incubation period, and the incidence of mortality and of paralysis among thiamin-deficient animals, are low (Rasmussen *et al.* 1943, 1944, Foster *et al.* 1944). Restriction of diet intake produces a similar but slightly less marked increase in resistance. Sprunt (1942) also records that undernourished rabbits are less susceptible than fully-nourished rabbits to vaccinia virus, and points out that viruses, which are highly adapted intracellular parasites, may be peculiar in requiring the full health of the host's susceptible cells for their proliferation. This peculiarity is not, however, confined to virus infections, for pantothenic acid deficiency is reported to be associated with an increased resistance to experimental infection with Type I pneumococci (West *et al.* 1944).

We cannot doubt that variations in the intake of B vitamins influence the course of infection by bacteria and viruses, though we cannot predict what the effect will be in any one type of infection; nor is it always possible to say the decrease in resistance is a specific vitamin effect. It should be noted that thiamin and riboflavin deficiency decreases resistance in rats to worm infection (Watt 1944) and biotin deficiency the resistance of birds to malaria (Trager 1943).

In man, riboflavin deficiency is associated with breakdown, fissuring and sometimes infection of the tissues at the angles of the mouth and in the naso-labial folds; and nicotinic acid deficiency (Sebrell and Butler 1939) with acute ulcerative stomatitis, in the lesions of which Vincent's organisms (see Chapter 80) may be found. A similar association of stomatitis, gingivitis and periodontal suppuration, with deficiencies of both the B_2 complex and Vitamin C, is reported in monkeys (Topping and Fraser 1939, Chapman and Harris 1941). There is little evidence to suggest that these infections are more than a secondary invasion of the superficial lesions associated with the vitamin deficiency.

Variations in the Intake of Vitamin C.—The evidence with regard to the effect of Vitamin C on resistance is peculiarly confusing and discrepant.

On the clinical side Hess (1920) stresses the frequency of infective complications in scurvy, while Bloch (1928) states that scorbutic children show no tendency to infection in any way comparable to that displayed by children suffering from xerophthalmia (see also Robertson 1934).

Fox and his colleagues (1940) found no difference in sickness rates of adult negroes receiving adequate Vitamin C and of those on a vitamin-deficient diet. Vogl (1937) reported that Vitamin C prevented the development of post-operative pneumonia, and that it hastened the convalescence of pneumonic patients (see also Sennewald 1938 Szirmai 1940). Beneficial results have been claimed also in the treatment of whooping cough (Ormerod and Unkauf 1937), though Gairdner (1938) in a carefully controlled test found no difference between untreated and vitamin-treated children. Bamberger and Zell (1936), Dieckhoff and Schüler (1938) and Szirmai (1940) also claim beneficial results in diphtheria. In most cases, however, the number of uncontrolled factors in these tests is large, and conclusions as to the specific action of the vitamin must be drawn with circumspection.

Glasebrook and Thomson (1942) provide one of the most clear-cut indications of a specific Vitamin C effect. They studied two groups of boys, one deficient in, the other saturated with, Vitamin C. They could find no difference in the incidence of common colds or tonsillitis in the two groups, but noted that deficient patients with tonsillitis stayed in hospital 16·7 days on the average, as against 16·0 days for the saturated patients. During the period of observation there were 17 cases of pneumonia and 16 cases of acute rheumatic fever among 1,100 deficient boys, and none among 335 saturated. The association of infection with low vitamin levels in animals or man is not in itself good evidence that the one is a direct result of the other, for in the infective state, especially when it is accompanied by fever, there is a decrease of the vitamin in the tissues; indeed, infection may precipitate scurvy in persons suffering from hypovitaminosis (see Abbasy *et al.* 1937, Harris *et al.* 1937, Fox 1943). The point is well illustrated in the attempts of Rinehart and his colleagues to reproduce the lesions of rheumatic fever in guinea-pigs. They found (1934) infection of scorbutic guinea-pigs with hæmolytic streptococci resulted in certain cardiac lesions which did not appear in scorbutic animals, or in normal animals infected with the streptococci. Moreover, in patients with rheumatic fever, the vitamin levels were unusually low (1936). McBroom and his colleagues (1937), on the other hand, observed the lesions in uninfected scorbutic guinea-pigs, provided that the scurvy was severe enough, and suggested that Rinehart's lesions were due to severe scurvy, precipitated in a non-specific manner by the superadded infection.

As regards spontaneous infections in guinea-pigs suffering from experimental scurvy, Hamburger and Goldschmidt (1922–23), Grant (1926, 1930) and Schmidt-Weyland and Költzsch (1927) state that they are very common. On the other hand, Holst and Frölich (1912) state that they are uncommon. The observations of Glenny and Allen (1921) on the occurrence of epidemic infection among a stock of guinea-pigs on a vitamin-deficient diet, and its suppression by the addition of a ration of green stuff, may perhaps be taken as relevant evidence, though we clearly cannot assume that C-avitaminosis was the determining factor.

As regards the resistance of scorbutic guinea-pigs to experimental infection, Findlay (1923), Werkman, Nelson and Fulmer (1924), Grant (1926) and Schmidt-Weyland and Költzsch (1927) record a slight increase in susceptibility. Findlay would ascribe this to the degenerative changes and feeble leucoblastic reaction seen in the bone-marrow of guinea-pigs suffering from chronic scurvy. Werkman, Nelson and Fulmer stress the association between lowered resistance and lowered body temperature.

The observations of Zinsser and Castaneda (1931) on the increased susceptibility of guinea-pigs and rats on a vitamin-deficient diet to experimental typhus infection may be referred to here. It is probable that the guinea-pigs were suffering from some degree of C-avitaminosis; but the fact that rats, which are generally regarded as being relatively insensitive to the deprivation of this vitamin, showed the same decrease in resistance makes it difficult to assess the significance of these results.

McCullough (1938) records an increased susceptibility to infection by *F. necrophorus* in deficient guinea-pigs, which only became evident when the scurvy was severe; the administration of Vitamin C was followed by prompt recovery. In man, major deficiency is associated with a retardation of fibroblastic activity and of wound healing (see Hunt 1941, Bourne 1942, 1944), and the possible association of vitamin deficiency and an inadequate cellular response to infection is evident in the observations of Meyer and Meyer (1944) on experimental *Staph. aureus* infection of guinea-pigs. In normal animals the abscesses produced were hard and circumscribed; those in scorbutic animals soft and with indefinite edges. The difference appeared to be due in the main to the extremely poor fibroblastic response in the scorbutic animals with a consequent failure in "sealing off" the abscess from healthy tissues.

Both bacteria and bacterial exotoxins are susceptible to the action of Vitamin C *in vitro*. The growth of diphtheria bacilli, streptococci, pneumococci, staphylococci, salmonellæ and *H. pertussis* is inhibited (von Gagyi 1936, Büsing 1939, Meyer 1939, Otani 1939).

Small amounts of diphtheria toxin are inactivated by Vitamin C (Harde and Philippe 1934, Greenwald and Harde 1935, Jungeblut and Zwemer 1935, King and Menten 1935, Widenbauer and Saretz 1936, Yokoyama 1938, Jungeblut 1941, Willison 1943). Jungeblut noted that the detoxication was increased in the presence of Cu ions. Petherick and Singer (1943) record a similar detoxication of *Cl. welchii* α-toxin, and of diphtheria and staphylococcal toxins, by Vitamin C in the presence of Fe, Cu, and Zn ions.

These observations have led to a number of tests on the protective effect of excess Vitamin C against diphtheria intoxication. The evidence for a protective action of the vitamin is conflicting. Neither Greenwald and Harde (1935), Widenbauer and Saretz (1936), Berger (1937) nor Zilva (1937) could detect any protective action in guinea-pigs; nor could Pakter and Schick (1938) detect any differences in the Schick-reactivity of normal children and children given massive doses of Vitamin C. Jungeblut and Zwemer (1935), King and Menten (1935), Lyman and King (1936) Yano (1938) and Jungeblut (1941), on the other hand, report that excess of the vitamin, given an hour or so before the toxin, will protect against 1–2 m.l.d. The protective effect was, however, inconstant. It appears that severe degrees of diphtheria intoxication reduce the vitamin content of the tissues (Torrance 1940; see also Lyman and King 1936). Vitamin C has little action on staphylococcal toxin (Mercier 1938) or that of *Cl. welchii* (Souto and Lima 1938), but inactivates the toxins of *Cl. tetani*, (Jungeblut 1937*c*, Kligler *et al.* 1938), *Cl. œdematiens*, *Cl. septicum* and *Cl. histolyticum* (Souto and Lima 1938). Souto and Lima claim that the vitamin has a prophylactic action in the animal against all four gas-gangrene toxins. Among the viruses we may note that Vitamin C inactivates herpes virus (Holden and Resnick 1936) and apparently increases the resistance of rabbits to dermal infection with the virus (Holden and Molloy 1937). It also inactivates vaccinia virus (Kligler and Bernkopf 1937). Jungeblut (1937*a*, *b*) has reported a marked diminution in the paralysis and death rates of poliomyelitic monkeys when treated with Vitamin C (see Chapter 87), but neither Toomey (1937) nor Sabin (1939) could confirm this result.

The *in vitro* action of vitamin C on infective agents and toxins can in most cases be ascribed to its considerable powers as a reducing agent. It seems unlikely that it could be given to the infected animal in sufficient quantities to produce in the tissues reducing intensities comparable with those in the test-tube, and we must ascribe any indubitable *in vivo* effect to a more complex action.

The same conflict of evidence holds with regard to the immunological consequences either of excess or deficiency of Vitamin C.

Lesné and Dreyfus (1911) and Zolog (1924) claimed that in guinea-pigs deficiency was associated with diminished sensitivity to anaphylactic shock. Cohen (1938) was unable to confirm these findings (see also Sartori 1925, v. Niekerk 1937). Several observers report a prophylactic effect of excess Vitamin C in guinea-pigs, both in the whole animal, and in isolated sensitized tissues (Lemke 1936, Solomonica 1936, Ungar, Parrot and Levillain 1937). Hochwald and Schwartz (1937), Raffel and Madison (1938) and Storck (1939) were unable to confirm these findings, and Dragstedt (Dragstedt *et al.* 1938) failed to find any effect of Vitamin C on hypersensitive dogs. Similarly with antibody formation; Jusatz (1936*b*) and Madison and Manwaring (1937) record enhancement of precipitin response in rabbits, and Raffel and Madison (1938) in guinea-pigs given excess Vitamin C. Hochwald and Schwartz (1937) found no enhancement in guinea-pigs immunized with horse serum, and Madison, Fish and Frick (1938) no effect on the response to bacterial antigens. (For a discussion of the relation between Vitamin C and serum complement, see Chapter 7.)

Variations in the Intake of Vitamin D.—The similar behaviour of Vitamin A and the anti-rachitic vitamin as regards their fat-solubility makes many of the earlier observations on the effect of a Vitamin D-deficient diet of doubtful significance.

Certain of the experimental studies that we have summarized above show that the addition of Vitamin D to a diet from which the fat-soluble vitamins have been removed does not prevent the lowering of resistance: indeed there is a suggestion in some of them (see Lassen 1931) that the addition of irradiated ergosterol increases the susceptibility of the animals receiving it. In other experiments Lassen found that rats on a rachitogenic diet not entirely lacking in Vitamin A showed no appreciable lowering of their resistance to experimental infection *per os*, even when the macroscopic and histological evidence of rickets was clear and unmistakable; and Freund (1932) was unable to demonstrate any significant difference in the resistance of rats and mice maintained on normal, Vitamin D-free or Vitamin D-excess diets. As we have noted above, a simultaneous deficiency of Vitamins A and D was found by Jusatz (1936*a*) to reduce the bactericidal power of the blood. Toomey (1937) protected monkeys against intestinally, but not intracerebrally, injected poliomyelitis virus by treatment with Vitamin D, but not with A and C, or the B complex. Sabin and his colleagues (1941), on the other hand, found that normal and rachitic monkeys were equally susceptible to the virus. By feeding puppies for 30–60 days on a diet containing excess of yeast and carotene, Frohring (1937) claimed to have increased their resistance to dog distemper so that none of them developed the disease when exposed in a distemper ward. The administration of a high vitamin diet apparently reduced the mortality in dogs that had contracted the disease. Scheunert and Petzold (1937) were unable to modify the susceptibility of puppies to experimental distemper by a diet rich in irradiated yeast, or to modify the severity of the disease by cod-liver oil or Vitamin B therapy. However, when the yeast diet was given to pregnant bitches, and maintained during weaning, the resistance of the puppies was increased.

If we attempt to assess the significance of the data at present available with regard to the influence of variations in vitamin intake on resistance to infection, we shall probably conclude (1) that there is good evidence that gross deficiency of Vitamin A is accompanied by a reduction of resistance; (2) that it is doubtful whether the addition of any extra source of Vitamin A to an ordinary unrestricted human or animal diet is likely to lead to any significant increase in resistance, save, possibly, in the special conditions of pregnancy, but that this question must await the answer of properly controlled trials carried out on an adequate scale; (3) that the evidence with regard to the effect of Vitamin C deficiency is so divergent that no sound conclusion is possible at the moment, though there are definite suggestions that animals such as the guinea-pig, that are peculiarly susceptible to the deprivation of this vitamin, are rendered more susceptible to infection when it is withheld; (4) that certain members of the B complex are associated with the factors that determine resistance and susceptibility; and (5) there is at present no satisfactory evidence that Vitamin D is associated with these factors.

The relation of resistance to infection and other members of the rapidly expanding class of accessory food factors has as yet hardly been explored in any precise manner, but the future will undoubtedly reveal significant relationships. (For more detailed general reviews of the literature see Lassen 1931, Clausen 1934, and Robertson 1934.)

The Influence of Other Dietary Factors on Resistance.

The variations in dietary factors which we review under this heading must not be understood to exclude variations in the vitamins. In many cases, the content of recognized vitamins in the diets is not itself known, and, in other cases, where they are known, effects that we wish to ascribe to certain energy-producing food materials may in fact be due to traces of unrecognized vitamins present in the diet. We may first summarize observations which seem to provide an unequi-

vocal experimental demonstration of an increase in resistance due to a change in diet, though the mechanism involved is, as yet, quite obscure.

Robertson and Doyle (1936) maintained three groups of rats on a basic diet of salts, cornstarch, vegetable fat, and vitamins in the form of cod-liver and wheat-germoils. Casein, wheat gluten and soya bean were added, respectively, to the diet in each group and the resistance of the animals was tested by intraperitoneal injection of *Salm. enteritidis*. The survival rates were 86 per cent. in the casein-fed animals, and between 30 and 40 per cent. in the two other groups.

Watson (1937) made a systematic study of the resistance of mice to infection with *Salm. typhi-murium*, and obtained significant results during the comparison of two diets, which differed in that 50 per cent. of the oatmeal supplied in one diet was, in the other, replaced by dried milk. In each case the diets were otherwise adequate and vitamins were supplied in the form of yeastrel and cod-liver oil. In repeated tests, carried out on statistically adequate groups of mice, it was found, with few exceptions, that the mice fed on the diet containing dried milk were significantly more resistant to the intraperitoneal injection of a toxic fraction isolated from *Salm. typhi-murium*. They were also more resistant to the administration by the mouth of living cultures of *Salm. typhi-murium*. They were not significantly more resistant to the intraperitoneal injection of living bacilli. The resistance to the injection of the toxin, and to the oral administration of moderately virulent cultures, was fully developed only in mice that had been fed since birth on the diet containing dried milk. It was detectable in mice that received the diet for three weeks before the test inoculation, but was in this case barely significant. The comparison was extended (Watson, Wilson and Topley 1938) to mice exposed to contact infection with *Salm. typhi-murium*. A significantly lower epidemic mortality occurred in the groups whose diets included the dried milk. The better diet apparently reduced the risk both of manifest, and of latent infection.

Church (1939) records results substantially in agreement with these using *Salm. enteritidis* as the infecting agent; he made the interesting observation that dietetic effects were far more readily produced in young mice if the mothers were also subjected to the diet from a few weeks prior to mating. Indeed, the only changes found to exert a significant effect when instituted first in the weaned mouse occurred as the result of a 75 per cent. decrease in the total mineral constituents or an 80 per cent. decrease in calcium content.

Reference to the protocols recorded by Webster and Pritchett (1924), by Pritchett (1927), and by Topley, Greenwood and Wilson (1931) will show that Watson's results were entirely compatible with the view that the milk powder in the diet was the component that determined the increased resistance of the mice receiving it, though this possibility was not in fact envisaged or discussed. How the effect is exerted it is not, as yet, possible to say. It seems, perhaps, more likely to be due to the effect on metabolism of a well-balanced diet, than to traces of any accessory substance in the dried milk; and it would appear that the tissue changes on which increased resistance depends take some time to develop.

Turning to studies that have so far yielded less definite and clear-cut results we may first consider certain surveys of a quite general kind, in which an attempt has been made to establish preliminary correlations that will serve to define problems rather than to solve them.

In this category fall the studies of Orr and Gilks (1931) on the health of two African tribes—the Masai and the Kikuyu—and related studies (Orr, MacLeod and Mackie 1931) on the effect of nutritional variations on the resistance of sheep. The Masai, particularly the males, live mainly on a diet of milk, meat and raw blood. The Kikuyu live almost entirely on cereals, roots and fruits. Apart from a marked difference in physique—the adult male Masai is 5 inches taller, 23 lb. heavier and 50 per cent. stronger than the Kikuyu

—there appears to be a significant difference in the frequency of certain types of infective disease; though the facilities for obtaining statistical data among native tribes are not of the kind that allow the collection of entirely convincing evidence. With this reservation, it would seem that pulmonary infections (bronchitis, pneumonia and phthisis) and tropical ulcer are far more frequent among the Kikuyu than among the Masai, while the latter are more prone to arthritis, presumably of an infective type. This difference in susceptibility to particular kinds of infection is associated with a low calcium content of the blood in the Kikuyu (9·4 mgm. per 100 ml. as against 11·4 mgm. among a small sample of Europeans in Kenya and 10–10·5 mgm. among Europeans in general). Samples of Masai blood could not be obtained on account of a tribal tabu. In the experiments on sheep, which were carried out in Scotland, animals were allowed to graze on different types of pasture, or fed on different diets in pens, and studies were made of the blood calcium, blood phosphorus, and (as an index of immunity *faute de mieux*) of certain of the natural agglutinating or lytic antibodies. The results, as one would expect, are by no means easy to interpret; but there appears to be a definite correlation between ample pasturage, a high calcium and low phosphorus content of the blood, and general well-being, and there is a suggestion that these conditions are associated with active lytic properties of the serum, while the agglutinins in certain experiments appear to have varied inversely as the lysins. In later experiments (Mackie *et al.* 1932) a slight indication was obtained that the animals on the poor pasture were more susceptible than controls to the intradermal injection of the toxin of the lamb dysentery bacillus.

It is noteworthy that experimental depletion of the serum proteins in dogs, by repeated bleedings and replacement of whole blood by erythrocytes alone, or experimental hypoproteinæmia and anæmia together, is associated with a high incidence of endocarditis, pneumonia and septicæmia (Robscheit-Robbins, Miller and Whipple 1943*b*). Mills and Cottingham (1943) found a marked decrease in the phagocytic activity of blood leucocytes in rats on a protein-deficient diet, and suggested that increased susceptibility to infection in these circumstances might be the result of depressed phagocytic powers.

The possibility that variations in the intake of *mineral salts* may have an influence on resistance has been explored by various experimental workers (Zilva 1919, Lange 1925, 1927*a*, *b*, Pritchett 1927, Hotta 1928, Kligler and Geiger 1928, Mayer and Sulzberger 1931, Sulzberger and Mayer 1931), but, excepting the results of Church (1939) noted above, the evidence is highly confusing. We can, at the moment, do little more than suspend judgment, and note that a question has been asked, but not answered.

We may pass to the effect of a general deficiency of food, apart from qualitative changes. We are here in little better case, so far as experimental evidence is concerned. Hotta (1928) records a definite decrease in the resistance of mice kept on a starvation diet, while Lassen (1931) finds only a trivial decrease in resistance of rats suffering from a relative but well-marked inanition for a period of 17 weeks (see also Müller and Simons 1919, Bieling 1925, Bickert 1931).

Apart altogether from their effect on the defence mechanisms of the tissues, there can be no question that variations in diet alter the local conditions in the gastro-intestinal tract. We know (see Rettger and Cheplin 1921, Dudgeon 1926) that the ingestion of certain food-stuffs produces characteristic changes in the gastro-intestinal flora; and Arnold (1926, 1927*a*, *b*, 1929) has stressed the importance of various food materials in deranging or maintaining the efficacy of the gastro-duodenal bactericidal mechanism, particularly in infants. He suggests that such results as those recorded by Webster and Pritchett (1924) and Pritchett (1927) may be due in part to effects of this kind.

We may note here an association between infection and hypersensitiveness to diet, which may prove to be of some importance in the study of resistance.

Coca (1941) has observed in man a syndrome that he ascribes to food allergy, and finds that the incidence of the "common cold" is higher among allergic than among non-allergic human beings. Brown and others (1943) have confirmed his observations.

The Influence of Fatigue on Resistance

In spite of the abundant clinical experience that establishes beyond question the conclusion that bodily rest is an important factor in the treatment of any infective disease, the experimental evidence with regard to the effect of fatigue on resistance to infection is more than a little puzzling.

Spaeth and his colleagues (Oppenheimer and Spaeth 1922, Nicholls and Spaeth 1922, Spaeth 1925) have published a series of observations carried out on rats and guinea-pigs, from which they conclude that the resistance of these animals to tetanus toxin, and to experimental infection with the pneumococcus, is increased as the result of the fatigue induced by making the animals run for a long period in a revolving cage. Bailey (1925) working with rabbits subjected to intratracheal inoculation with pneumococci either before or after exercise, found that severe exhaustion increased their susceptibility to infection. There were indications that repeated intermittent exposures to the fatiguing process rendered the animals refractory to the depressant effect of fatigue. Friedberger and others (1931) have injected rats and guinea-pigs intraperitoneally with El Tor vibrios and have compared the fate of resting animals with that of others fatigued before, or after, or both before and after, the inoculation. There was no significant difference in mortality among the different groups. In the same series of experiments these authors studied the effect of fatigue on antibody production. The results were entirely negative. Such observations must clearly be interpreted conservatively, and without uncritical generalization. They emphasize the stability of the defence mechanisms of the tissues under a variety of different stresses; but they do nothing to lessen the significance of our common experience that fatigue is harmful in established infections, and it would be very unwise to conclude from them that fatigue has no influence on the liability to contract an infection under natural conditions.

More illuminating are the experiments recorded by Boycott and Price-Jones (1926). It may be noted that the infection they studied—that produced by *Salm. enteritidis* in the rat—is a natural disease of that animal, and therefore far more analogous in its pathogenesis to natural human infections than are the experimental conditions selected for study by the workers referred to above. When rats were infected with *Salm. enteritidis* by subcutaneous or intraperitoneal inoculation, fatigue induced before the inoculation, or during the first few days after it, appeared to have very little effect on the subsequent mortality rate. But when the rats were infected by feeding and then fatigued on several occasions during the subsequent few days the results were quite different. Twenty-seven rats were treated in this way and of these 13 died. Twenty control rats were fed on the same cultures, but were not subsequently fatigued; of these none died. The animals that survived the whole period of observation were submitted to necropsy, and it was found, in conformity with the findings recorded by many other observers, that the majority of them were still harbouring *Salm. enteritidis* in the spleen. There is an obvious suggestion that fatigue has a significant effect in activating a latent infection and favouring its fatal generalization.

The Effect of Variations in Temperature, Humidity and Other Physical Conditions of the Environment

The evidence available under this head is concerned mainly with the effect of these environmental factors on the first-line defence mechanisms of the kind considered in Chapter 45. Arnold and his colleagues (Arnold 1927*b*, 1928, 1929,

Arnold and Brody 1927) have studied in considerable detail the effect of high temperature, especially when associated with high humidity, on the gastro-duodenal bactericidal mechanism of the dog. They find that such conditions are associated with a decrease in gastric secretion, a consequent fall in the acidity of the gastric and duodenal contents, and an increased passage of bacteria from the stomach or duodenum to the cæcum.

There are in the literature many other records of experiments on the effect of temperature and humidity on resistance to infection (see McDowell 1923, Kligler and Olitzki 1931, Robertson and Weld 1932, Nishikawa 1935), but the numbers of animals in the comparable groups are so small, and the effects of these two factors seem so difficult to disentangle, that the significance of the results reported cannot be assessed.

Hill and Muecke (1913) have shown that the mucosa of the human nose becomes turgid with blood and covered with a thick, mucous secretion when subjects are exposed to a warm, moist atmosphere, and that when such subjects pass immediately to a cold atmosphere the mucosa pales quickly as the result of a constriction of the vessels, but remains swollen and œdematous for a considerable period. Mudd and his colleagues (1921) have found that chilling of the body surface is associated with a marked fall of temperature in the nasal and post-nasal cavities, and that the return to the normal temperature in these situations is at first rapid, but then very slow, when the body surface is again warmed. There is, then, good evidence of significant changes in the physiological conditions of the nose and nasopharynx in response to changes in temperature and humidity, and it may well be that some of these changes are associated with a lowering of the local resistance; but such a correlation will clearly be very difficult to establish by any statistical survey of naturally occurring infections, and we have as yet no experimental data bearing directly on this point. Nungester and Klepser (1938) demonstrated that exposure to cold increased the aspiration of mucous material into the lungs of white rats; that non-infective doses of pneumococci would infect the lungs of rats when introduced together with mucin; and that though chilling by itself did not lower the resistance of rats to intraperitoneal pneumococci, it greatly increased the incidence of pneumonia in rats inoculated intranasally with mixtures of pneumococci and mucin. They concluded that chilling, by increasing the aspiration of mucous secretions from the upper respiratory tract, might favour the occurrence of pneumonia.

Though they are not concerned with the direct effect of cold, we may note the experiments of Locke (1937) who observed that the more rapidly rabbits recovered their body temperature after artificial chilling, the greater was their resistance to subsequent intravenous and intradermal infection with pneumococci. Here the chilling was employed as an independent test of the physiological response of the animals to an adverse environment. Duerschner, Muschenheim and their colleagues (Hardy *et al.* 1943, Duerschner *et al.* 1943, Muschenheim *et al.* 1943) have recently reported upon the effect of severe chilling in experimental tuberculosis and in pneumococcal infections. Rabbits and guinea-pigs were held under anæsthesia for 6 to 24 hours at 4°–8° C., twice weekly for several weeks. The treatment had no effect on the development of tuberculosis in guinea-pigs, though there was a marked delay in the appearance of skin sensitivity to tuberculin. The response of chilled and normal rabbits to an intradermal lethal dose of virulent pneumococci was similar, except that the local lesions were smaller in the chilled animals. When less virulent pneumococci were injected, chilling resulted in inhibition of the local lesion, and a fatal bacteræmia. The rapid invasion of the blood stream did not appear to be solely due to the absence of a local response, for in other experiments, chilling was found to reduce the minimal lethal dose even of intravenously injected pneumococci.

Among other physical agencies mention may be made of the possible effect of ultra-violet irradiation of the body surface since this procedure has been advocated as a means of increasing resistance to infection. We have noted (p. 1175) that

Colebrook, Eidenow and Hill (1924) have demonstrated a temporary increase in the bactericidal power of the blood as the result of exposure to ultra-violet rays, and a similar effect after exposure to dark heat, or to the blistering of the skin with a mustard plaster. The general experience of the beneficial effect of sunlight as enjoyed under optimal natural conditions, combined with such observations as the above, made it natural to inquire whether any isolated constituent of the solar radiation, and particularly the rays of short wave-length, would produce a significant increase in resistance to intection. Some favourable views have been recorded (Maughan and Smiley 1928, 1929, Hill and Laurie 1931) ; but the balance of evidence appears to be very definitely against the view that exposure to such rays has any significant effect.

Barenberg and Lewis (1928) report entirely negative results in a small group of infants. Colebrook, D. (1929), in a very careful and detailed study carried out on school children of 5–7 years of age, compared the frequency of infection (1) in a group of 101 children irradiated 3 times a week with light from a carbon arc lamp with a high output of ultra-violet rays, (2) in a group of 94 children irradiated under the same conditions except that light of wavelength shorter than 3,200 Å.U. was cut off by a glass screen, and (3) in a group of 92 children who received no irradiation. Over the period of observation—August 1927 to March 1928—the number of colds per 100 child-weeks' exposure to risk was 20·2 in the group irradiated without screening, 18·7 in the group irradiated with the screened lamp, and 18·6 in the control group. The average duration of each cold was 7·5, 7·5 and 7·1 days respectively. The incidence of measles among those exposed to risk and not previously attacked —a small group—showed no significant difference between the treated and untreated: the attack rates were 80·0 per cent. in those irradiated without screening, 70·6 per cent. in those irradiated but screened, and 68·2 per cent. in the unirradiated controls. In the case of whooping cough the attack rates were 8·8 per cent., 7·7 per cent. and 8·6 per cent. In no case did the irradiated group show any benefit. A later report by Doull, Hardy, Clark and Herman (1931) is entirely confirmatory. It deals with a careful study of the frequency of colds among irradiated and unirradiated groups of volunteer students, or members of the staff, at Johns Hopkins University. Every statistical precaution was taken in planning the trial and in assessing its results. These were unequivocal. Among 169 persons in the irradiated group, the attack rate during the period September 29, 1929 to May 31, 1930 was 78·6 per 1,000 student-weeks ; among 184 persons in the unirradiated control group it was 71·9. Whatever test was employed—duration of colds, the presence of fever, the presence of cough or sputum—or whatever allowance was made for previous history or differences in physical conditions, the result was the same: the irradiated group showed no advantage.

The experimental data available are, so far as they go, in accord with field observations. Chapman and Hardy (1931) were unable to obtain any evidence that irradiation increases the resistance of rabbits to the subcutaneous injection of *Pasteurella lepiseptica*. Hill, Greenwood and Topley (1930) found that irradiation conferred no benefit on mice submitted to contact infection with *Pasteurella muriseptica*.

Antibody Formation.—It is convenient at this point to mention recent work on the modification of antibody response. We have already cited a few examples of dietary influences on this function. Scaglione (1938) concluded from a study of rabbits and young children that Vitamin A favoured the agglutinin response to T.A.B. vaccines. Schmeckebier (1943) reports an increase of diphtheria antitoxin in the blood of women given Vitamins A and D. General dietary deficiencies can also modify antibody response. Thus Hartley (1943) found that the substitution of mangolds for cabbage in a basal diet consisting of cabbage, bran and hay, reduced the response of stock guinea-pigs to diphtheria

toxoid (see also Schmidt and Fjord-Nielsen 1934). Cannon, Chase and Wissler (1943) compared the agglutinin response to *Salm. typhi* in normal rabbits and rabbits rendered hypoproteinæmic by partial starvation and by continuous removal of blood plasma and found that the titres of the normal animals at about 8 days were 3 to 5 times greater.

The antibody response in cold-blooded animals like the fish is more effective at high than at low temperatures (see Cushing 1942). Kopeloff and his colleagues observed changes in sheep-cell hæmolysin production in rats after section of the thoracic spinal cord at a high level, but were able to control the variations by maintaining the animals at a constant temperature. Rats kept with their body temperature 5° C. below normal responded poorly to the antigen; raising the temperature to normal was followed by a rise in hæmolysin within 36 hours (Kopeloff and Stanton 1942, Stanton *et al.* 1942). Hartley, Evans and Hartley (1943) investigated the effect of chilling, restricted diet, and infection with *Cl. welchii*, on the secondary response of guinea-pigs to diphtheria toxoid. The experiments were undertaken to estimate the probable effect of adverse conditions of the battlefield on the response of wounded soldiers to " boosting " doses of tetanus and other toxoids (see Chapter 77). Neither a restricted diet, nor daily exposure to temperatures of 2° C. appeared to affect the magnitude of the response to the stimulating dose of toxoid. There was, however, some evidence that the clostridial infection had depressed the response.

Ellingson and Clark (1942) report a series of experiments to test the response of various defence mechanisms to temperatures greater than normal. In rabbits the artificial induction of a severe fever (41·5° C.) slightly reduced the antibody response during immunization with various antigens. It also produced a slight acceleration of the rate of disappearance, and presumably, of destruction of antibodies in the blood stream. Phagocytosis of *Staph. aureus* by human and guinea-pig leucocytes was only slightly depressed at 42° C.; and in rabbits injected intradermally with lethal doses of virulent pneumococci, the maintenance of artificial fever until the infection itself reached the febrile stage made no significant alteration in death rate, survival time or degree of bacteræmia.

Seasonal Variations in Resistance

Seasonal variations in the frequency of particular infective diseases are a commonplace of epidemiology. How far such variations are dependent on fluctuations in the average resistance of the host species, how far on environmental factors that increase the opportunities for the spread of infection, and how far on factors the nature of which we cannot even guess, are problems to which we can as yet give no answer.

Observations are on record from which the conclusion has been drawn that seasonal changes in the efficacy of the normal defence mechanisms do in fact occur (see Pritchett 1925, 1926, Glenny and Waddington 1928, Blake and Okell 1929, Mayer and Sulzberger 1931, Sulzberger and Mayer 1931, Orr, MacLeod and Mackie 1931). Wilson (1930) has noted synchronous fluctuations in the mortalities following the injection of three different strains of *Salm. typhi-murium* into mice during a sixteen months' period, each strain being tested on 15 occasions. It appeared impossible to relate these synchronous changes in mortality to any common factor acting on the three bacterial strains, and it seemed difficult to escape from the view that they must have been due to synchronous transient fluctuations in the resistance of the mice, but these fluctuations showed no definite seasonal distribution.

Even if the occurrence of seasonal variations in resistance were clearly established, it would be an exceedingly difficult task to disentangle the various factors involved; and without such disentanglement there could be little hope of intelligent interference. The vitamin content of foodstuffs, and many other dietetic variables, are subject to seasonal influences; the condition of the nasal mucosa and the

efficiency of the gastro-duodenal bactericidal mechanism are, as we have seen, affected by changes in temperature and in humidity; and there is little doubt that many other types of physiological response, of which as yet we know little or nothing from the immunological viewpoint, may be subject to influences of a similar kind. Until our knowledge of the relative significance of these factors, working in isolation, is much more accurate and detailed than it is at present we can hardly hope to construct a useful working chart of the total effect of the environmental changes associated with the changing seasons.

The Effect of Certain Chemical Substances in Favouring Bacterial Infection

We may include in this chapter a brief survey of a series of observations that have, during recent years, focussed attention on certain chemical substances that play a significant part in the local pathogenesis of infective lesions. It is becoming increasingly clear that some of these factors exert an important influence on the frequency and severity of naturally occurring infections, particularly in industrialized communities.

As a first example we may cite the observations of Bullock (Gye) and Cramer (1919) on the effect of calcium salts in certain anaerobic infections, and the more recent studies of Fildes (Fildes 1927, 1929*a*, *b*, Knight and Fildes 1930, Campbell and Fildes 1931). Bullock and Cramer found that ionizable salts of calcium, inoculated together with the washed spores of *Cl. welchii*, of *Cl. tetani* or of certain other anaerobes, led to the development of the corresponding infections in their most typical and fatal forms, while the washed spores alone showed no tendency to develop in the tissues after inoculation. The chlorides of sodium, potassium, ammonium, strontium or manganese had no such effect. They were unable to determine the exact mechanism by which this effect, to which they gave the name *kataphylaxis*, was brought about; though they were able to show that it was not due to an absence of leucocytes from the lesions, nor to a lack of phagocytic activity on the part of the cells that collected at the site of inoculation. Fildes (1927), attacking the particular problem of experimental tetanus in the guinea-pig, studied the vegetation of spores in the normal testicle, after ligation of the blood vessels. He found that the injection of tetanus spores into the ligated testicle was followed by a rapidly fatal toxæmia, indicating rapid vegetation in the tissues. Comparison of sections from ligated and unligated testicles, at various intervals after the injection of the spores, showed that active vegetation had occurred in the ligated testicle at a period when emigration of leucocytes was at its earliest stage in the unligated testicle, and therefore before any significant degree of phagocytosis could in any case have occurred. He concluded that there must be some definite stimulus to vegetation in tissues cut off from their blood supply, either by ligation of vessels or by the vascular injury following the injection of calcium salts, and suggested that this stimulus was probably the result of the diminished oxygen tension, although Bullock and Cramer had tentatively rejected this view. Later (Fildes 1929*b*) he carried out a detailed study of the oxidation-reduction potential of the tissue fluids under different conditions using suitable indicator dyes. He found that oxidized methylene blue injected into the subcutaneous tissues of the living guinea-pig is not reduced, while reduced methylene blue is rapidly oxidized. In the dead animal the oxidized methylene blue undergoes a slight reduction, while the reduced methylene blue is not oxidized. Analogous results were obtained with thionin and with indophenol I. The general conclusion may be drawn that, in the subcutaneous tissues of the living guinea-pig the oxidation-reduction potential (Eh) at the prevailing pH of about 7·0 is in the neighbourhood of + 0·12 volt, while, as shown in a previous communication (Fildes 1929*a*), tetanus spores will not germinate readily at a potential more oxidizing than + 0·01 volt at this pH (see also Knight and Fildes 1930). In further experiments it was shown that the injection of solutions of calcium chloride

led to the production of localized areas of oxygen deficiency, with an Eh on the negative (reducing) side of that of methylene blue, thus providing conditions suitable for the germination of tetanus spores. Campbell and Fildes (1931) studied the effect of other methods of varying the oxygen pressure of the tissues. Guinea-pigs were maintained in atmospheres containing different partial pressures of oxygen (60 per cent., 20 per cent. and 7 per cent.) and in air containing 0·15 per cent. of carbon monoxide. Control experiments showed the corresponding pressures of oxygen in the subcutaneous tissues (in mm. Hg) to be approximately 26, 20, 5 and 6. When animals subjected to these atmospheres were injected intramuscularly with a mixture of tetanus spores and aleuronat the animals maintained in atmospheric air (20 per cent. oxygen) showed a mortality of 45 per cent., those maintained in an atmosphere of 60 per cent. oxygen a mortality of 6 per cent., those contained in 7 per cent. oxygen, or in air containing 0·15 per cent. CO, a mortality of 75 per cent. These results clearly support the view that the oxygen pressure of the tissues controls the germination of the tetanus spores.

Bullock (Gye) and Cramer (1919) noted that the local defence rupture produced by the injection of calcium salts favoured infection with streptococci, as well as with anaerobic bacilli. The nature of the effect has been studied in more detail by Kettle (1927). Here again there is no evidence of any diminished emigration of leucocytes, or lessened phagocytic activity, and the main effect of the calcium, as revealed by histological examination of the lesions, is a striking increase in the rate of bacterial multiplication. As Kettle points out, the streptococcal-calcium lesions in the mouse bear a close resemblance to the rapidly spreading streptococcal cellulitis that occurs in man. It would appear that the characteristic exudative lesion that is caused by the calcium salt provides peculiarly favourable cultural conditions for streptococci, as it does for anaerobic bacilli; though it does not, of course, follow that the two effects are determined by identical chemical or physical factors.

Calcium is not the only substance which produces defence rupture. That silica has an injurious effect on the lungs and that there is an association between silicosis and tuberculosis has been known for some 30 years, and Gardner (1920) has shown experimentally that a dust containing a high percentage of silica has a significant effect on pulmonary tuberculosis in the guinea-pig. The factors concerned in this enhancement of tuberculous infections by silica have been studied in detail by Kettle (see Gye and Kettle 1922, Kettle 1924, 1926, 1927, 1930, 1932).

The majority of these experiments have been carried out on mice. These animals are normally far more resistant to tuberculosis than is the guinea-pig; and the selective action of silica can be readily demonstrated by subcutaneous injection of the material under test followed by an intravenous injection of living tubercle bacilli. Silica, or silica-containing material, is injected at one spot, some other substance to act as a control at another. If the control substance is an irritant, such as calcium chloride or turpentine, the bacilli that are injected intravenously appear in both the silica and control lesions, but it is in the silica lesion that they show the most active proliferation. The hypothesis of a specific action by the silica is clearly supported by the fact that the more extensive calcium lesion provides far less favourable conditions for the growth of the tubercle bacillus; and by the results of careful comparative tests on a large number of industrial dusts (Kettle 1932), which show that it is the presence of silica, or of a silicate, that determines the characteristic effect. Crystalline silica, unlike colloidal or amorphous silica, is very slowly dissolved in the tissues, and only when dissolved does it exert its injurious action. Silica crystals coated with oxide of iron are not dissolved in the tissues, and they remain inert and harmless.

The pathogenesis of the lung lesions of silicosis, and the association of this condition with tuberculosis, have been studied in numerous experiments in which dusts have been brought in contact with the lung tissue of guinea-pigs or rabbits, either by repeated or

prolonged inhalation, or by the direct injection of a suspension of the dust into the trachea (Kettle 1930).

An interesting experiment is recorded by Gardner (1930). Guinea-pigs were infected, by inhalation, with a strain of tubercle bacillus of unusually low virulence, which normally produces in these animals a retrogressive type of tuberculosis confined to the lungs and bronchial glands. The infection is practically never fatal. When animals so infected were exposed for 8 hours a day to quartz dust an entirely different picture was produced. After 3 to 5 months the bacilli in the lungs began to proliferate actively. The infection spread to all parts of the lungs and to the abdominal viscera, producing large and progressive lesions. The bacilli had not become more virulent, since cultures isolated from the dusted animals produced the usual type of retrogressive tuberculosis when administered to normal undusted guinea-pigs. Vorwald and Delahant (1938) record not only that tuberculosis in the guinea-pig and rat develops with greater vigour in animals treated with silica, but that the immunizing effect of heat-killed tubercle bacilli is inhibited by the simultaneous injection of silica.

Until recently it had been generally assumed that the silica, and the lesions it produced, sensitized the tissues to tuberculous infection. The silica, that is to say, had been regarded as the primary active agent. Kettle (1934) has shown that this view needs considerable modification.

Different groups of guinea-pigs were injected intratracheally with a suspension of silica alone, a suspension of avirulent tubercle bacilli alone, and a mixture of silica and avirulent tubercle bacilli. The dust alone produced a catarrhal reaction, but relatively little fibrosis, and nothing resembling the characteristic nodular silicosis of man. The avirulent tubercle bacilli alone produced relatively little tissue reaction. The mixture of silica and tubercle bacilli produced a characteristic nodular tuberculo-silicosis, closely similar to the human disease. It would seem that the typical silicotic lesions are induced not by silica acting on a normal lung but by the joint action of silica and some bacterial infective agent; and Kettle suggests that the natural human disease should be known as infective silicosis.

Experimental studies of the kind outlined above open up wide fields for further exploration, and we may reasonably hope to obtain light on many problems by studying the ways in which infections may be modified as the result of the local or general action of various chemical agents. Two contributions along these lines may be noted.

Findlay (1928) has attempted to test the tentative hypothesis that the localization of pathogenic bacteria, or of filtrable viruses, at the site of localized tissue injury might be the result of the liberation of histamine, or of histamine-like substances, from the injured tissues, leading to a localized dilatation of the capillaries and an increased permeability of the capillary endothelium. Animals of a susceptible species were inoculated intravenously with an infective agent—the virus of fowl-pox, or of vaccinia, or of the Rous sarcoma, *Staph. aureus*, *Str. hæmolyticus*, or the pneumococcus—and histamine acid phosphate in a 0·5 per cent. solution was then injected into a site suitable for the observation of any lesion, the same amount of phosphate-buffer solution being inoculated into a corresponding site on the opposite side of the body to serve as a control. In each of the experiments the lesions appearing at the site of the histamine injections were significantly more frequent and more severe than those appearing at the site of injection of the phosphate-buffer solution. The latter were indeed infrequent in occurrence and minimal in degree.

Rosher (1931) has studied the effect of the growth-promoting factors (X and V) on experimental infection with *H. influenzæ* in mice. When a suspension of influenza bacilli in ordinary nutrient broth was used for intraperitoneal inoculation, 26 per cent. of 45 strains killed one or more of five mice. When 0·05 ml. of Fildes' solution (containing both

growth factors) was added to the inoculum, 71 per cent. of these strains killed one or more mice.

Effect of Mucin on Bacterial Infection.—Nungester and his colleagues (1932, 1936) noted an exaltation of pathogenicity of pneumococci and streptococci when injected intraperitoneally with a suspension of gastric mucin. Mucin proved to be particularly effective with bacteria which, like meningococci and gonococci, are not naturally pathogenic to laboratory animals, and which were lethal only in doses in which the total amount of bacterial toxins introduced in the infecting dose, not multiplication and spread of the bacteria, was primarily responsible for the death of the animals (Miller 1933, Miller and Castles 1936, Cohen 1936). A similar exaltation of pathogenicity was observed in *H. influenzæ* (Fothergill *et al.* 1937), *Salm. typhi* (Buttle *et al.* 1937), *H. pertussis* (Silverthorne 1938), typhoid bacilli (Rake 1935) and *Staph. aureus* (Anderson and Oag 1939) but not in *Myco. phlei*, " *B. anthracoides*," *Myco. smegmatis*, *Str. viridans* or *Bact. coli* (Anderson and Oag 1939). Substances like agar, starch and gelatin have a similar though less marked effect (Miller and Castles 1936; for negative results with a variety of substances, see Anderson and Oag 1939). The exaltation of pathogenicity produced by the mucin was not accompanied by any demonstrable change in the virulence of the bacteria, but was clearly due to some action on the defence mechanisms of the animal. The efficacy of the mucin has been variously reported as due to its viscosity and power to inhibit intraphagocytic digestion of the bacteria (Nungester *et al.* 1936); to its power to injure the defensive cells and inhibit phagocytosis (Miller and Castles 1936); to its interference with sensitization of the bacteria by antibody (Keefer and Spink 1938). Anderson and Oag (1939) and McLeod (1941) concluded that viscosity alone was not a determining factor, since other more viscous substances were inactive. Activity depended more on the chemical state of the mucin, particularly in the " protein " fraction. According to McLeod, who worked with meningococcal infections, if mucin is to be effective it must be present in adequate amount, and be slowly absorbed from the peritoneal cavity; it promotes infection mainly by permitting the survival and growth of the organism in the peritoneal cavity, but to some extent inhibits the bactericidal action of serum, as well as intraphagocytic digestion, and, if present in granular form, mechanically interferes with the phagocytosis of the bacteria. It may be noted that the viscous, undegraded Group A blood substance isolated from gastric mucin by Morgan and King (1943) behaves like gastric mucin in this respect, and that both viscosity and the power to enhance pathogenicity are lost with the chemical degradation of this substance.

We may conclude this section with reference to benzene and alcohol, two substances that have been employed experimentally to assess the relative importance of the local inflammatory response and of specific antibodies in the defence against infection. In the rabbit, poisoning with benzene reduces or inhibits the local inflammatory response of the skin; there is little hyperæmia, little exudation, and little or no mobilization of leucocytes. More generally, there is an inhibition of leucocyte formation in the bone marrow, and a blood leucopænia. In poisoned animals with no specific immunity, infective organisms (e.g. pneumococci or streptococci) spread rapidly from the site of intradermal injection, and more readily produce fatal generalized infection. Benzene does not apparently interfere with antibody formation, and specific antibodies, whether actively or passively acquired, will to some extent check the spread of bacteria from the local lesion in the absence of leucocytes (Camp and Baumgartner 1915, Hektoen 1916, Rich and McKee 1934, 1939, Schnitzer and Goddard 1943, Schnitzer 1943). Alcohol poisoning also inhibits the normal inflammatory response to local infection. Pickrell (1938) concluded from a study of actively immunized rabbits that the alcohol directly inhibited the reactivity of the capillaries to irritants, thereby preventing a mobilization of leucocytes at the site of a subcutaneous infection with Type I pneumococci. The presence of antibodies in the local inflammatory site was not conspicuously protective in the absence of leucocytes. Lushbaugh (1943) confirmed Pickrell's results in the main, but could not produce a com-

plete suppression of the inflammatory response to intradermally injected pneumococci. Thus the phagocytic response was greatest in the immune, normal rabbit, less in the immune alcoholic, and least in the non-immune alcoholic rabbit. Antibody to some extent protected the alcoholic rabbits, presumably by checking the local infection long enough for the sluggish tissue defences to mobilize.

Nungester and Klepser (1938) demonstrated an increased susceptibility to intranasally injected pneumococci in rats acutely intoxicated with alcohol. They found that the leucocytes of the intoxicated rats had lost their positive chemiotaxis to pneumococci. They concluded, however, that in addition to a generalized depression of the defence mechanisms, the increased susceptibility was probably due in part to the anæsthesia induced by the alcohol, which permitted a readier inhalation of infective material into the lung.

The Influence of Hormones on Resistance to Infection.

There is little doubt that resistance does vary with different states of hormonal balance in the animal body, but the data are for the most part too confused to yield any clear picture of the hormonal effect. The hormonal variations that have received greatest attention in connection with resistance to infection are those of the sex hormones. It is not our purpose to review the literature of sex incidence and mortality in infective disease, nor to consider the variations in resistance that accompany puberty, menstruation, pregnancy and sexual senility; but to give some examples from recent experimental work illustrating the kind of hormonal effects that have been observed.

Schütze, Gorer and Finlayson (1936) record a definite, but inconstantly observed superiority of female mice over male mice in their resistance to infection with *Salm. enteri, tidis* and *Salm. typhi-murium*; but a male superiority in resistance to infection with *Past. muriseptica*. Watson, Wilson and Topley (1938) also noted that female mice were more resistant than males to the epidemic spread of infection with *Salm. typhi-murium*. There are a few experimental studies of the effect of the female sex hormones on resistance. Rosahn, Hu and Pearce (1936) found that male rabbits were less resistant to vaccinia infection than female, and non-pregnant females less resistant than pregnant females. Jungeblut and his colleagues report that poliomyelitis virus was inactivated *in vitro* by a preparation from the urine of pregnant mares and by the serum of the same animals. They were unable to obtain any clear evidence of protection by various hormones in experimental poliomyelitis of the monkey (Jungeblut, Meyer and Engle 1934, Jungeblut and Engle 1934). Aycock (1936) records that œstrin protected 5 of 6 castrated female monkeys against an otherwise fatal dose of poliomyelitis virus, an effect he attributed in part to the thickening and proliferation of the site of injection—the nasal mucosa—under the influence of the hormone. A similar effect may be responsible for the curative action of œstrin in gonorrhœal vaginitis in children. The cells of the immature vaginal mucosa are poor in glycogen; with the onset of puberty, or with the administration of œstrin, they become rich in glycogen, and superficial keratinization occurs. In the œstrin-treated child with vaginitis, the pH of the vaginal contents shifts from about 7·0 to 4·5–6·0, the pus cells and gonococci disappear, and only epithelial cells and Döderlein's bacilli are found (Lewis 1933, Nabarro and Signy 1935, Lewis and Adler 1936; and for later references, see Burpee *et al.* 1939). Apart from the sexual effects of the œstrin, the treatment is on the whole successful. The elimination of the gonococci is attributed in part to the greater resistance of the "mature" keratinized epithelium, and, more generally, to the acidity of the vaginal contents, which is probably the result of lactic acid production by Döderlein's bacillus from the cellular glycogen (see Chapter 90).

In spite of the body of evidence pointing to a modification of the course of syphilis by pregnancy, Kemp (1937) was unable to modify experimental syphilis in rabbits by the administration of œstrogenic hormones. Moderate degrees of protection against

pneumococcal infection were reported by von Haam and Rosenfeld (1942) in white mice of both sexes given injections of œstrone or of testosterone propionate several days previously.

The work of Sprunt and his colleagues provides an interesting example, not only of a hormone effect on resistance, but a relatively simple explanation of how the effect is produced. He observed that the œstrogenic hormone, when injected for a period of 3 weeks into castrated rabbits, decreased the spread of intradermally injected india ink, and increased the resistance of the animals to intradermal vaccinia virus. Pseudopregnant females showed the same phenomenon (Sprunt, McDearman and Raper 1938, Sprunt and McDearman 1940*a*, *b*). The effect appeared to be the reverse of that produced by the Duran-Reynals spreading factor (see Chapter 44) which, when injected with suitable doses of vaccinia virus, increases the degree of skin infection in proportion to the increase in the lateral spread of infective fluids from the injection site. Sprunt (1941) later showed that the interstitial fluid in rabbits was increased by the administration of the hormone, and that the excess fluid in the tissues was responsible both for the failure of vaccinia virus to infect, and of india ink to spread in the skin. More recently Taylor and Sprunt (1943) have reproduced these two effects in rabbits treated by a course of intraperitoneal injections of hypotonic salt solution.

It is clear that we may in the future expect detailed and fruitful analysis of the relations of hormones and resistance. At present these few examples will serve to show the reality of the relation, and some of the ways in which the hormonal effect may possibly be brought about.

The Enhancement of Resistance to Infection by Sulphonamides.

The full discussion in Chapter 6 of the mode of action of sulphonamides on bacteria makes it clear that, of all the hypotheses of the curative action of these drugs, the hypothesis of a direct, *in vivo* antibacterial action has the first claim on our attention. It is in fact widely held that the sulphonamides enable the body defences to eliminate infection by exerting a lethal or bacteriostatic action on the invading organism, or by making it in some way more susceptible to the natural antibacterial defences of the tissues; direct action on the tissues is confined to the toxic effects of overdosage of the drug, and in some cases an interaction of drugs and tissues to yield a different antibacterial substance, as in the breakdown of sulphonamido-crysoidin (Prontosil) to yield active sulphanilamide. The hypothesis is generally acceptable on the grounds that (*a*) the *in vitro* and *in vivo* activity of the various sulphonamides are broadly the same, and (*b*) that the activity of a given sulphonamide varies with the species and often with the strain of the infecting organism. If sulphonamides directly stimulated the body defences, we should expect a greater similarity of action in various infections than is actually the case. The recorded discrepancies between *in vivo* and *in vitro* activity of any one drug and a given bacterium (see, for example, Buttle *et al.* 1937, Gley and Girard 1937) do not necessarily invalidate the hypothesis, for it is seldom possible to make a precise comparison of the concentrations of drugs and drug-antagonizers, and of bacteria, in the test-tube and the tissues, or to assess the contribution made by the tissues to the antibacterial effect.

Various *in vivo* sulphonamide effects on the invading bacteria have been postulated. Capsular degeneration of pneumococci and streptococci was observed by Levaditi and his colleagues (1935*a*, 1939), by Telling and Oliver (1938) and by Whitby (1938), though Long and Bliss (1937*a*), Gay and Clark (1937) and Lyons and Mangiaracine (1938) did not observe it in streptococci, nor Fleming (1938*b*) in pneumococci. Capsular degeneration, it should

experimental *Cl. welchii* and *Cl. septicum* infection, and no synergy in combined drug and antitoxin treatment.

To summarize, the main action of the sulphonamides appears to be directly antibacterial, thereby diminishing the degree of damage produced in the tissues by the infecting bacteria and permitting the more effective action of the natural mechanisms of defence against infection; there is no good evidence of a direct stimulation of the tissue response. Antibody response is modified in so far as the amount or nature of the antigenic stimulus of the invading organisms is altered by the drug; and in certain circumstances, where the tissue responses play a large part in the elimination of infection, the presence of specific antibody appears to enhance the therapeutic effect of the sulphonamides.

The Enhancement of Resistance to Infection by other Substances.

As far as the facts are available, the arguments we have briefly sketched in favour of a purely antibacterial action of the sulphonamides *in vivo*, hold also for the *in vivo* action of the sulphones and other synthetic chemotherapeutic substances, and for penicillin (see p. 184) and other natural antibacterial agents. We cannot exclude the possibility that some of the active substances may prove to be direct stimulants of the tissue defences. It is to be noted, however, that a direct stimulation of this kind is unlikely to be found commonly among substances which, in the current methods of chemotherapeutic research, are selected primarily for their *in vitro* antibacterial properties.

We may note here three recorded examples of protective action by substances not usually regarded as chemotherapeutic.

Wohlfeil (1937) reports that the injection of large prophylactic doses of ferrous salts will protect guinea-pigs against a lethal dose of virulent *C. diphtheriæ*. Treatment after infection prolonged the life of the animals, but did not prevent their ultimate death. The effect was apparently associated with the heavy metallic ion, since sodium and magnesium salts were inactive. The ferrous salts also improved the immune response of guinea-pigs to toxoid and to living bacteria (Wohlfeil and Becker 1938). It seems probable that this effect is analogous to the adjuvant action of other substances in antibody formation, discussed on p. 1115.

The addition of stable emulsions of oil in water to bacterial exotoxins (Walsh and Frazer 1934, Myers 1934, Oerskov and Schmidt 1935) and to cobra venom (Frazer and Stewart 1938) renders them non-toxic on injection into susceptible animals. The detoxication is apparently due to absorption of the toxin at the oil-water interface (Frazer 1936). Frazer and Stewart (1940) noted that mixtures of emulsion and cobra venom were harmless when injected intravenously, but lethal intraperitoneally. It appeared that the emulsion was unstable in the peritoneal cavity, and the venom-interface complex was disrupted with liberation of the toxin, while in the blood stream the serum proteins maintained the stability of the emulsion. It is not yet clear how far the emulsions will protect against or modify established intoxication in the animal.

Finally, simple chemicals may be used to protect susceptible tissues against the entry of an infecting agent. Armstrong (1935, 1936, 1937, Armstrong and Harrison 1936) reported that the nasal instillation of alum or picric acid protected mice against intranasal infection with the St. Louis encephalitis virus, and monkeys against intranasal infection with poliomyelitis virus. Schultz and Gebhardt (1937) found that zinc sulphate was similarly effective against poliomyelitis. The rationale of these procedures is the direct modification of the olfactory area so that it is insusceptible to penetration, or infection, by the virus. The insusceptibility, however, appears to be achieved at the expense of considerable damage to the nasal mucosa (Schultz and Gebhardt 1942, see also Chapter 87).

The Rôle of the Bacteriophage in Infection and Resistance

This is, perhaps, as convenient a place as any to summarize the available evidence with regard to the rôle played by the bacteriophage, or rather by bacteriophages, in infection and resistance. In Chapter 11 we discussed the nature of these lytic agents, and concluded that the balance of evidence was definitely in favour of the view that they are filtrable viruses, parasitic on, or symbiotic with, various species or strains of bacteria. The relationship between the various types of phage and the bacteria that are sensitive to their action is often highly specific; and this specificity seems to be determined, in many cases at least, by the nature of the antigenic components that are situated at the bacterial surface.

The existence of living viruses, specifically attacking various pathogenic bacteria, offered an obvious possibility that they might be employed in the prevention or cure of infective disease. That they can, in fact, be so employed, and are highly effective, has been claimed by d'Herelle (1926); and several observers have reported favourable results in field trials of cholera phage as a prophylactic in India (see Morrison 1932). There are also various observations in the literature with regard to the use of phages as therapeutic reagents in human infections (see Krueger and Scribner 1941); but these are discrepant, and not of the kind that provide us with the evidence we need, though on the occasions when large-scale observations are made with as great a care as the circumstances permit, the results are not encouraging (see Boyd and Portnoy 1944). Moreover, aside from a theoretical lethal action of the phage on the infecting bacteria, it is possible that the phage filtrates are beneficial because they act as specific vaccines, since they contain the antigens of lysed bacteria; as stimulants of a non-specific immunity; or as opsonins (see Krueger and Scribner 1941). In this last connection we may note that MacNeal, McRae and Colmers (1938) demonstrated a marked opsonic effect when optimal quantities of specific phage were mixed with *Staph. aureus* and added to human blood. Until some years ago there was on the experimental side little evidence that phage had an *in vivo* antibacterial action, excepting a few observations suggesting that phages injected into an animal simultaneously with such organisms as *Salm. typhi* or *Bact. coli*, had a slight protective action (Wollman 1925, Arnold and Weiss 1926, Walker 1929).

Thus there was a general failure to demonstrate any protective or curative action of phage filtrates against *Salm. typhi-murium* or *Salm. enteritidis* when tested in mice (Topley and Wilson 1925, Topley *et al.* 1925, Levy 1925, Wollman 1925, Richet and Hauduroy 1925, Bronfenbrenner and Korb 1925–26, Ebert and Peretz 1929, Greenwood *et al.* 1936). Similarly, phage filtrates had little or no protective or curative action in salmonella infections in fowls (Pyle 1926), in experimental plague in rats (Compton 1928, 1930, Doorenbos 1929), in hæmolytic streptococcal infections in rabbits (Clark and Clark 1927) or in guinea-pigs (Colvin 1932), or in experimental anthrax in the mouse (Cowles and Hale 1931). Nor was there any experimental evidence that the presence in the intestines of mice of a phage acting on *Salm. typhi-murium* prevents the spread of natural contact infection with that organism (Topley and Wilson 1925, Topley *et al.* 1925, Greenwood *et al.* 1936).

In 1937, Asheshov, Wilson and Topley provided clear-cut evidence of a protective and to some extent a curative action of phage. A mixture of $1{\cdot}5 \times 10^9$ particles of a Vi phage, and 10^8 living virulent typhoid bacilli of the Vi type was held for 10 minutes *in vitro*, and proved innocuous on intraperitoneal injection into

mice. The protective effect was specific, and depended on the presence of active Vi phage. Intravenous phage was also fully protective against intraperitoneal bacilli, when given at the same time; it was protective when given two, but not four, hours after infection.

These results have been confirmed by Fisk (1938), Yen and Chang (1941), Pio de Roda and Saqueton (1941) and Ward (1943). Asheshov and his colleagues pointed out that the typhoid infection in their mice was a highly artificial disease, the lethal dose of bacilli being large and producing an acute toxæmic death. Ward overcame this objection to some extent by using mucin to enhance the virulence of the typhoid bacilli, so that 10–100 organisms were lethal. Intravenous phage, 2 hours after infection, proved highly protective against this type of infection. The protection did not appear to be due to stimulation of phagocytosis, nor to any immunizing power of the phage filtrate. There was some evidence that actual *in vivo* lysis of the infecting bacteria occurred, and a marked increase of circulating phage occurred some hours after its injection. The healthy survivors among the treated mice carried the typhoid bacilli for some weeks, but many of the organisms on isolation proved to be degraded variants without Vi antigen. That the protective action of phage is accompanied by its apparent multiplication *in vivo* is clear from the experiments of Rakieten and Rakieten (1943) and of Dubos and his colleagues (1943). The former protected 10-day-old chick embryos from a fatal infection with *Sh. flexneri* by a single dose of specific phage, and found an association between survival of the embryos and a demonstrable increase in their phage content. The latter injected Shiga dysentery phage into the peritoneal cavity of normal mice, and found that the phage content of the tissue rose to a maximum in 2 hours and then declined rapidly; the phage content of the brain was much lower than that of the blood. When the phage was injected into mice inoculated intracerebrally with *Sh. shigæ*, the phage content of the brain increased rapidly till it exceeded that of the blood, and reached a maximum in 12 hours. At the same time the mice were protected against an otherwise fatal meningitis. Oral phage afforded no protection.

These results have been achieved by the administration of very large numbers of phage particles, and in special experimental circumstances. Their applicability to the therapy of natural infective disease is still to be determined, and the problem of the great discrepancy between the high *in vitro* and the low *in vivo* activity of a given phage is still unsolved.

One possible reason for the failure of therapy is the development in the tissues of phage-resistant variants of the infecting bacterium (see Chapter 11). In the experiments cited above, both Ward (1943) and Rakieten and Rakieten (1943) noted the presence in phage-treated tissues of variants that were presumably induced by the action of phage, but they appeared to have little virulence. On the other hand, strains of *Salm. typhi-murium*, isolated from mice that have died of infection in spite of the presence of phage in the tissues, have proved just as sensitive to that phage as the bacteria originally inoculated (Topley and Wilson 1925 Topley *et al.* 1925, Greenwood *et al.* 1936).

Blood, serum, bile, white cells, tissue debris can all inhibit lytic action of phage *in vitro* (see Evans 1933, Applebaum and Patterson 1936, Zaytzeff-Jern and Meleney 1936). Little, however, is known of the mechanism of phage inhibition. It may be (see Zdansky 1924) that the cells or colloids of the body fluid exert *in vivo* an inhibiting effect on phage lysis similar to the inhibition exerted *in vitro* by high concentrations of gelatin or agar (Bail 1922, Doerr and Berger 1922, Otto and Munter 1923, Bronfenbrenner and Korb 1925). This suggestion is supported by the observation that hitherto the most hopeful results of bacteriophage therapy

have been obtained in cholera—a disease in which the infecting vibrios are multiplying freely in the watery contents of the intestine.

In any case, until we know more than we do of the factors that prevent any but high concentrations of phage from exerting any protective effect in the tissues, we cannot justifiably conclude that it is impossible so to adjust the conditions that a large part of the *in vitro* activity might be made available for therapy in the infected animal.

SUMMARY

(1) With regard to the effect on resistance of variations in diet, the one fact that stands out clearly is that a gross deficiency in the intake of Vitamin A, especially during the period of rapid bodily growth, is associated with a marked increase in susceptibility to infection. There are suggestions that C-avitaminosis, in animals peculiarly liable to this condition, may be associated with a similar break in resistance; and that resistance can be to some extent restored by the administration of the vitamin; but the evidence is highly confusing. There is little consistent evidence that the *in vitro* antibacterial and antitoxic action of the vitamin is reflected in a prophylactic action of excess vitamin against infection or intoxication. In certain cases resistance is altered by deficiency of one or other of the B vitamins, sometimes in the direction of increased susceptibility, and, in certain virus diseases, in the direction of increased resistance. There is no good evidence that a deficiency of Vitamin D has any significant effect on resistance. There is little if any evidence that an excess of Vitamin A, above the limit required to prevent the occurrence of detectable avitaminosis, has any prophylactic or therapeutic effect in infective disease, with the possible exception that some prophylactic effect may be exerted by the administration of Vitamin A during the late stages of pregnancy.

(2) Our knowledge of the influence of other dietetic factors on resistance to infection is as yet too scanty to justify any general conclusions. Recent observations show that certain food substances, like dried milk, when added to an otherwise adequate diet increase the resistance of mice to certain bacterial toxins, and certain bacterial infections; and it seems clear that this is not a direct vitamin effect. Studies of this kind are, however, in their infancy.

(3) In general, it is only the dietary deficiencies, whether of vitamins or foodstuffs, of a degree leading to manifest deterioration of the general bodily health, which are unequivocally associated with depression of resistance to infection, and inhibition of the cellular and antibody responses to the invading organisms.

(4) The experimental evidence with regard to the influence of fatigue on resistance suggests that it is more important as a factor leading to the activation of a latent infection than as predisposing to infection *ab initio*.

(5) The data with regard to the effect of variations in the physical environment are scanty. It is certain that fluctuations in temperature and humidity affect the local conditions in the upper part of the respiratory tract, and it seems possible that the changes produced may in some cases lower the local resistance. There is evidence that similar environmental changes may derange the gastro-duodenal bactericidal mechanism. Prolonged exposure to cold appears to depress the defensive tissue responses to infection. There is no satisfactory evidence that irradiation with ultra-violet rays produces any significant increase in resistance to natural or experimental infection.

(6) There are suggestions that a seasonal variation may occur in the general resistance to infection. If this be the case, such fluctuations are probably dependent on variations considered in the previous sections; but which factors are concerned or what their relative importance may be we cannot tell.

(7) Evidence is accumulating with regard to the importance of certain chemical substances as agents favouring local infective processes. Thus ionizable calcium salts favour the germination of tetanus spores in the tissues, and this fact is of importance in aiding the natural pathogenesis of tetanus in wounds grossly contaminated with soil. Silica favours the local proliferation of the tubercle bacillus in the tissues, and is an important predisposing cause to this infection in certain industrial populations. The mechanisms upon which these kataphylactic effects depend have been subjected to detailed study with results of considerable interest and importance. Chemotherapeutic agents like the sulphonamides, and natural antibacterial substances like penicillin, do not directly stimulate the defence mechanisms of the infected animal. Their action is predominantly if not exclusively antibacterial. Nevertheless, their total therapeutic effect depends to a substantial though varying degree upon the natural cellular and humoral antibacterial responses of the tissues.

(8) Under controlled experimental conditions, bacteriophages have been shown to be both protective and curative *in vivo*. There is as yet little evidence of successful phage therapy of natural infections, except perhaps in cholera.

CHAPTER 55

IMMUNITY IN VIRUS DISEASES

THE virus diseases of man and animals are described in Chapters 85 to 89, and that description includes the immunity reactions that occur in each particular infection. It is, however, even at the cost of some repetition, desirable to summarize and discuss the available data with regard to immunity to virus diseases as a whole, as contrasted with immunity to bacterial infections. There was a tendency among earlier workers to differentiate somewhat sharply between immunity to these two classes of parasite ; and this differentiation involved, mainly by assumption, the mechanisms brought into play as well as the quality and duration of the immunity induced. The problem that mainly concerns us here is the extent to which this differentiation is justified. Almost all experiments on the transmission of virus infections, and on immunity reactions *in vivo* or *in vitro*, have of necessity been carried out with tissue extracts or with other crude material containing host products as well as virus. Under these conditions the qualitative or quantitative analysis of such reactions is rendered very difficult, and for this reason the study of antiviral immunity has tended to lag behind that of antibacterial immunity at just those points in which the latter has become most precise. We have, however, learned enough of the mechanisms concerned to construct a useful working outline which can be filled in rapidly when our technical difficulties have been overcome, and which has already passed the sound empirical test of enabling us to interfere with considerable success in the natural propagation of infection.

Antiviral Immunity as Observed under Natural Conditions. Latent Infections.

The first fact that forces itself on our attention when we examine the natural history of virus diseases is the frequency with which an effective and lasting immunity is afforded by a single attack (see Andrewes 1931). Smallpox, chickenpox, measles, mumps, cattle plague, swine fever, and dog distemper—all these are common virus diseases, and all confer an immunity that, in the great majority of cases, appears to last throughout life. There are exceptions. Herpes simplex is one ; influenza and the common cold are others. Not long ago foot-and-mouth disease would have been placed in this non-immunizing or poorly immunizing class ; but we have had to reconsider our views in that regard, and perhaps the relations that have misled us in this instance have misled us in others also. It is well to remember, as Bedson (1937) points out in his valuable review, that the mechanism of immunity probably varies with different types of viruses, as it does with different types of bacteria, and that generalizations about the similarity or difference of immunity in bacterial and virus diseases are apt to be misleading.

Though, at one time, the idea was prevalent that infection with a pathogenic

virus invariably resulted in a frank case of the disease, diagnosable by ordinary clinical methods, it has become increasingly clear of late years that atypical, abortive, and latent infections are very common and play an important part in the genesis of naturally acquired immunity. Even in so highly contagious a disease as measles, there is evidence to show that not every susceptible child who is exposed to infection contracts the disease.

Stocks (1928, 1930*a*, *b*), in a series of careful analyses of the relevant data, has shown that the morbidity figures for measles, for chicken-pox and for German measles are inexplicable except on the assumption of immunization in the absence of diagnosed disease, or of an effective inherited immunity. That the former factor is operative can be demonstrated by comparing, during any epidemic prevalence, the attack rate among children who have previously been intimately exposed to risk without contracting the disease with that among children who have previously been less intimately exposed. The natural history of these widely prevalent virus diseases, as developed by Stocks, presents striking analogies to the natural history of diphtheria or of scarlet fever.

In other virus diseases the occurrence of atypical cases and of healthy carriers has obtained general recognition. Wickman (1907), for example, pointed out that it was impossible to account for the epidemiological behaviour of poliomyelitis without assuming the existence of latent and atypical infections; and Stocks (1932), examining the available data of several outbreaks, calculates that the ratio of those developing latent immunizing infections to those developing clinical attacks of the disease is probably of the order of 100 to 1 or more.

In support of the epidemiological evidence is the finding that protective antibodies acting on the poliomyelitis virus are widely distributed among the population at large.

Aycock and Kramer (1930*a*, *b*, *c*), using the highly susceptible monkey as a test animal, determined the protective power of samples of serum obtained from convalescent cases and from normal persons. Some 90 per cent. of the former and just over 50 per cent. of the latter showed protective antibodies in the serum. Similar tests were later carried out on normal persons, giving no history of poliomyelitis, living in another area of the United States. Of 21 adults, 18 showed neutralizing antibodies in their blood. Brodie (1932) has recorded similar findings in Montreal.

If we accept the view that the presence of such antibodies indicates previous contact with the virus of poliomyelitis we can hardly escape the corollary that mild atypical attacks, or a purely immunizing carrier infection, must be an exceedingly common event in this particular disease. Some observers, however, believe that protective substances occur in the serum of normal persons apart altogether from any specific stimulus (see Jungeblut and Engle 1932*a*, *b*, 1933, 1934, Jungeblut 1933, 1934). The problem is analogous to that of the origin of the natural antibacterial antibodies (see Chapter 49).

In addition, there are now several reports of the isolation of poliomyelitis virus from the nasal secretions or fæces of healthy carriers (Flexner *et al.* 1913, Kling and Pettersson 1914, Lépine *et al.* 1939, Kramer *et al.* 1939, Langmuir 1942).

Yellow fever is another disease in which latent infections appear to be very common. Serum protection tests in South America and West Africa have shown that in endemic areas, where clinical cases are infrequent and sporadic, a high proportion of the children show neutralizing bodies in their blood, indicating that the overt cases of disease give a quite erroneous picture of the real frequency of infection (Beeuwkes *et al.* 1930, Russell 1932, Hughes and Sawyer 1932, Soper *et al.* 1932, Mahaffy *et al.* 1933, Beeuwkes and Mahaffy 1934).

The degree of latency may be even more striking.

In lymphatic choriomeningitis of mice, for example, infection of every mouse in a particular stock occurs, either *in utero* or soon after birth, giving rise to few or no symptoms, and remaining latent for the rest of the animal's life. Antibodies are not usually developed, and the persistence of the virus can readily be demonstrated by inoculation of tissue extracts into mice of a non-infected stock (Traub 1936*a*, *b*, 1938, 1939). In this instance an almost perfect equilibrium appears to be established between the virus and its host.

In Virus III infection of rabbits, and in some of the mouse pneumonia virus infections, a similar state exists, but the presence of the virus can be brought to light by repeated passage through normal or infected animals, the virus ending by giving rise to characteristic disease in the host (see Andrewes 1939).

So far, we have been considering latent infections in healthy persons or animals. Attention must now be drawn to the persistence of virus in convalescent patients who have suffered from a typical or atypical form of the disease in question. Here again the degree of latency varies to some extent.

Herpes febrilis virus, for instance, often affects young children, giving rise to stomatitis. Such patients are liable to recurrent attacks throughout life of herpes labialis, particularly in association with colds, pneumonia, and certain fevers. The virus appears to lie latent in the tissues between attacks, and to flare up on receipt of the appropriate stimulus. Antibodies are demonstrable in the blood, but they have apparently little or no effect in preventing a relapse (Dodd *et al.* 1938, Burnet and Lush 1939*a*). In poliomyelitis and yellow fever, on the other hand, the persistence of the virus is associated, as a rule, with a solid immunity. The poliomyelitis virus has been isolated from convalescents several months after the disease; and in yellow fever the probable persistence of the virus may be conjectured from the finding of antibodies in patients many years after an attack of the disease, even when no contact with the active agent has occurred in the meantime (see Rivers 1943). Psittacosis in experimentally infected mice, and infectious anæmia of horses, are two other examples in which the virus seems to remain indefinitely in the tissues after it has given rise to an attack of the disease. In neither of these infections are neutralizing antibodies evident to any extent, and it is easy therefore to demonstrate the presence of the virus by inoculation of a tissue suspension or a drop of blood into a susceptible animal.

There is strong reason to believe that in these and many other virus diseases the continuance of a solid immunity is dependent upon persistence of the virus in susceptible cells of the body. The transient nature of the immunity that develops towards virus diseases of the respiratory tract, such as the common cold and influenza, may perhaps be due to the desquamation of the surface cells of the mucosa, which cannot therefore afford a permanent home for the infecting viruses (Rivers 1943).

The Mechanism of Virus Infections.

It would appear that the general process of tissue invasion in virus diseases does not differ in any essential way from that described in the case of bacterial infections. There would seem, in many cases at least, to be the same sequence of local proliferation, blood-stream invasion and secondary foci of infection, each phase varying in prominence according to the virulence of the virus and the susceptibility or resistance of the host.

Thus, Todd and White (1914) note that, when cattle are injected subcutaneously with a small dose of the virus of rinderpest, the blood usually remains non-infective for 72 hours, becoming infective coincidently with the onset of illness; and Andrews and others (Report

1931) note that the virus of foot-and-mouth disease does not appear in the blood of experimentally infected cattle until shortly before the commencement of the febrile reaction, though it may be present in high concentration some hours before the temperature begins to rise, or before vesicles appear. The virus then tends to persist in the blood throughout the febrile period, though the degree and persistence of blood-stream infection varies widely in different animals (see also Waldmann, Trautwein and Pyl 1931). In the case of yellow fever, Hudson and Philip (1929) record that monkeys bitten by infected mosquitoes show the presence of virus in their blood 1 to 2 days after infection, and at about the same interval before the onset of fever.

Vaccinia, as regards its obvious lesions, is commonly limited to the site of inoculation into the skin ; though the virus may be recovered from the blood after intradermal inoculation in the rabbit (Ohtawara 1922, Rivers and Tillett 1923, Gildemeister and Heuer 1927), and Gins and his colleagues (1929) have reported its presence in the nasal secretion of children after ordinary cutaneous vaccination. With highly potent strains of virus a generalized vaccinia may occur after dermal inoculation in the rabbit, with a widespread eruption, pocks on the lips and tongue, and lesions in the lungs, liver and other organs (Douglas, Smith and Price 1929). When such a virus is injected intravenously this severe, and sometimes fatal, generalization occurs with considerable frequency, and there is a rough proportionality between the dose of the virus administered and the degree of resultant generalization. When less potent viruses are injected intravenously there is frequently some degree of generalization, evidenced by an eruption of pocks on previously shaved areas of skin or on the mucosa (Calmette and Guérin 1901, Camus 1917–18, Levaditi and Nicolau 1923).

On the other hand, in the more strictly nervous diseases, such as rabies, there is no evidence to suggest that local proliferation or blood-stream invasion occurs ; the virus appears to gain access to the central nervous system by way of the axis cylinders, and to diffuse through the brain and cord entirely by nervous paths. There is no exact analogy to this behaviour in the diseases caused by bacteria, though the route of diffusion appears to be closely paralleled by tetanus toxin.

Many viruses have naturally a strong selective affinity for certain tissues, such as the vaccinia virus for the cells of the epidermis and the poliomyelitis virus for the anterior horn cells of the cord. It is customary to speak of such viruses as *dermotropic* and *neurotropic* respectively. Others, such as the yellow fever virus, which affects particularly the liver, are sometimes spoken of as *viscerotropic* ; and others, such as the psittacosis virus, which affect tissues widely distributed throughout the body, as *pantropic*. All these terms are relative and are easily abused. In general, they are of more value when referring to the properties of different strains of the same virus than in comparing different viruses. By passage experiments and other means variants of a given strain may be developed that show considerable differences in their tissue localization and in their pathogenicity. Examples are the street virus and the fixed virus of rabies, and the viscerotropic and the neurotropic variants of the yellow fever virus.

The histopathology of the virus diseases, though differing in some respects from that of most bacterial infections, does not differ so sharply and fundamentally as to require a separate generic description. There is only one characteristic peculiar to the viruses, namely their ability to form *inclusion bodies* in the cells they invade. Even this is essentially similar to the intracellular multiplication of such an organism as the leprosy bacillus, the resulting colonies differing in no material way from the virus colonies of which the cytoplasmic inclusion bodies are composed. The tissue lesions that are associated with virus infections—inflammatory, necrotic, degenerative, granulomatous and proliferative—are of the same kind as those that

follow infection with one or other of the pathogenic bacteria ; and the stress of the reparative reaction appears to fall on the same cells of the reticulo-endothelial system (see Ledingham 1924, 1926*a*, *b*, 1927, Ledingham and Barratt 1929).

Of the ultimate mechanisms by which the filtrable viruses produce their harmful effects we as yet know little or nothing. We do not, for instance, know whether any of them produce soluble toxins with a characteristic pharmacological action, such as are produced by certain bacteria. Until our technique has developed to the point at which we can secure mass cultivation *in vitro*, in a cell-free medium, this problem is likely to remain unanswered. We can at the moment go no further than the statement that no instance has as yet obtruded itself upon our notice in which it seems necessary to assume the presence of a soluble toxin acting at a distance from any focus of living virus. On the other hand, there is some evidence to suggest that endotoxins, similar to those contained in certain bacteria, may be produced by viruses. Rake and Jones (1944), for example, have found that the lymphogranuloma, meningopneumonitis, and mouse pneumonia viruses (see Chapter 85), when grown in the yolk sac of the developing chick embryo, may elaborate a thermolabile endotoxin, which is capable on intravenous inoculation into mice of causing death in 4 to 24 hours.

Antiviral Immunity.

Before discussing the mechanism of antiviral immunity it will be convenient to consider briefly the ways in which such immunity may be induced ; since it is held by many that, in this respect, there is a significant difference between the behaviour of the filtrable viruses and bacterial cells.

Active Antiviral Immunity.—As regards active immunity, we have seen that this is conferred under natural conditions by a typical attack of the disease, and probably by atypical attacks of varying severity or by a carrier infection. Artificially it may be induced by the injection of a sublethal dose of living virulent virus (a dangerous and uncertain method, even when injections are made by an unusual route), by the injection of a virus that has changed its disease-producing characters, but not its antigenic structure, during adaptation to a different host-species—the classical example is the use of vaccinia to protect against variola—or by an initial injection of a fully attenuated virus followed by injections of less and less attenuated samples until the fully virulent virus is resisted—the classical example is the Pasteurian method of protection against rabies by the injection of rabbit-cord virus attenuated by drying. The question at issue is whether we can induce an effective antiviral immunity by the injection of killed virus alone, in the way that we can produce an antibacterial immunity by the injection of killed bacterial cells. The question really resolves itself into two others. Can we produce an effective resistance by the injection of virus-containing material so completely inactivated that it produces no detectable infection when injected in large doses into a fully susceptible animal ? If this is possible, may we assume that the inactivated virus is actually dead ?

We may answer the first question affirmatively, provided we qualify it by saying that the immunity produced by an inactivated virus is seldom of long duration, unless it is followed up by a later injection of active virus.

Semple (1912) has shown that the classical Pasteurian methods of rabies prophylaxis may be replaced by injections of rabbit-brain virus inactivated by treatment with 1 per cent. phenol. Boynton (1918, 1928) records successful immunization against cattle plague with

a phenolized vaccine, Curasson and Delpy (1926) and Daubney (1928) with a vaccine inactivated with formol. Ducloux and Cordier (1926) report successful immunization against sheep-pox with vaccines inactivated by formol or by ethanol. Bedson, Maitland and Burbury (1927) record the partial immunization of guinea-pigs against foot-and-mouth virus by the injection of formolized virus, and the complete immunization of a proportion of animals after prolonged treatment. Todd (1928*b*), having failed to immunize fowls by the injection of heat-killed or formolized fowl plague virus, succeeded in producing an effective immunity by the injection of three doses of a phenolized vaccine. Bedson (1931) produced a high degree of immunity in guinea-pigs against herpes by the injection of a formolized virus and records similar results with inactivated psittacosis virus (see Discussion 1932). Other examples will be found in vaccines against distemper, Rift Valley fever, equine encephalomyelitis, and influenza.

It would seem a fair conclusion that the injection of inactivated virus material almost always confers some degree of specific resistance, provided that a suitable method of inactivation is employed; but that the resistance so conferred varies widely in effectiveness in different virus diseases. In some it is of a high order. In others it must be reinforced by injections of active virus; and it is probable that such reinforcement always increases the solidity and duration of the resistant state.

When we inquire whether an inactivated virus may be assumed to be a dead virus, we are on more difficult ground. There is general agreement that the application of violent, and therefore certain, methods of killing—such as heating to high temperatures for long periods—destroys the antigenic value of virus-containing material. Indeed, as we have seen above, inactivation by such a chemical agent as formol may remove the antigenic value of one virus but not of another. Such facts are, perhaps, in favour of the view that attenuation rather than death marks the limit beyond which we cannot pass if an effective antigenic stimulus is to be obtained; but they are also explicable on the assumption that the lack of immunizing effect is due to some alteration in an important antigenic constituent rather than to the killing of the virus. If all effective vaccines were attenuated, not killed, we might expect occasional infections with our treated vaccines. In some instances at least such accidents seem never to occur. Thus (see Harvey and McKendrick 1930), the testing of 500 samples of Semple's phenolized rabies vaccine by the injection of 1 ml. intramuscularly into rabbits did not result in a single infection. Similarly, if a symptomless infection occurred in an animal injected with an inactivated vaccine, it might be possible by passage from that animal through others to produce characteristic symptoms or lesions. Bedson (1931) notes that his formolized herpes vaccine produced no lesions when introduced into the plantar skin of guinea-pigs, nor was it possible by passage from animal to animal by this route to restore its activity. Even these results are not entirely convincing, since it might plausibly be maintained that the chemical treatment had affected the virulence of the virus without destroying its vitality. Failure to grow in tissue culture or in the developing chick embryo might be a more convincing test. Taking the evidence as a whole, however, we may agree with Bedson (1937) in regarding, for all practical purposes, such inactivated viruses as dead. But when we look more closely into our terms we are faced with the difficulty of defining "living" and "non-living" in relation to viruses. This is a question that need not detain us here; it has already been discussed in Chapter 41 (see p. 967).

Whatever the final verdict may be, it is the common practice at the moment to rely on the injection of living virus under the protection either of a partial active immunity induced by the previous injection of virus inactivated in some appropriate way, or of a temporary passive protection induced by the injection of serum from an immunized animal. The latter method is very commonly employed, and its practical exploitation has led to some interesting observations. These have been admirably summarized by Andrewes (1931).

Virus-serum mixtures incubated until infection can no longer be produced by any route seem to be useless as immunizing agents. To be effective they must be slightly under-neutralized. In this state they will produce immunity against some virus diseases. A more generally effective method is the so-called side-to-side inoculation—virus into one site, serum into another. Depending upon the ratio of antiserum to virus, this procedure may be followed by a mild and atypical infection or may produce no detectable general reaction. In some cases effective immunity is secured only if the serum-virus ratio is within the range at which a generalized reaction occurs; in others, such as dog distemper (Laidlaw and Dunkin 1931), an excess of antiserum sufficient to suppress such a reaction does not prevent a successful immunizing response. Side-to-side immunization has been successfully employed in cattle plague (Kolle and Turner 1898, see also Carmichael 1928), swine fever (Dorset *et al.* 1919) and dog distemper (Laidlaw and Dunkin 1931). Theiler (1907-1909) records the successful immunization of horses and mules against African horse sickness by the simultaneous intravenous injection of virus and antiserum.

Another effective method is to administer the antiserum after the virus. This involves a mild immunizing attack of the disease, and for this reason it will clearly never be a method of choice where times and conditions may be determined at will; but it has an important application when exposure to risk of infection has already occurred, or is an imminent and unavoidable danger. By the administration of antiserum in adequate amount, and at the correct interval after exposure, it is possible to avoid a severe and typical attack, replacing it by a trivial infection that will confer a lasting immunity. The modern methods of measles prophylaxis (see Chapter 88) afford an excellent example of successful action along these lines.

Passive Antiviral Immunity.—Turning to passive immunity, enough has already been said to indicate that antiviral sera are at least as effective in affording protection against the homologous virus as is an antibacterial serum in protecting against the homologous bacterium. It may be noted that, while antibacterial sera are commonly prepared by the immunization of some conveniently large animal, usually the horse, it has become the practice to prepare antiviral sera by the immunization of an animal of the same species as those it is desired to protect. This is in part due to the fact that much of the work on virus diseases has been carried out within the province of veterinary medicine, and that the original observations on the protective power of immune sera were made with the blood obtained from convalescent animals, or from such animals after further treatment with large injections of active virus. These hyperimmunized animals, when of a conveniently large kind, provide a supply of highly effective antiserum. There are, moreover, many observations which suggest that homologous antisera may be more effective than those prepared in animals of another species. Thus an antidistemper serum prepared in the dog will protect both dogs and ferrets against distemper virus, but protection in the ferret is much less effective and less consistent than in the dog (Laidlaw and Dunkin 1931). [Cf. the efficacy of different antisera in passive anaphylaxis, p. 1140.]

As in antibacterial immunity, the passive immunity so obtained is transient—too transient to be of any prophylactic value except under narrowly limited conditions that only occasionally occur in practice.

There are observations on record—some of them contained in the papers already referred to—indicating that antiviral sera may have a definite if limited therapeutic value, though there is reason to believe that once virus has gained access to the cell no circulating antibody, whether generated actively by the host or passively introduced, is able to neutralize it.

The Mechanisms of Antiviral Immunity.

We know very little of what happens when a virus is introduced into the tissues of a resistant animal, or when a relatively avirulent strain is injected into a relatively susceptible animal. We cannot, therefore, construct any detailed pictures of the kind outlined in Chapter 47 in the case of bacterial infections.

Our ignorance on this point is due to technical difficulties rather than to lack of interest. In the case of bacterial infections we can, by staining and by cultivation, trace the distribution of the parasites in the tissues with considerable accuracy. In virus diseases neither method is available in a form suitable for this purpose, and we are thrown back on the inoculation of a susceptible animal whenever we wish to demonstrate the presence of virus in a given tissue. If we desire our results to be quantitative—as we usually do—we are in further difficulties unless the virus produces a characteristic skin reaction. If it does, we can titrate it with some approach to accuracy. If it does not we have to rely on producing infection or death in an adequate sample of animals with each dose tested, and our task becomes formidable. Nor do our troubles end here. The material we inject contains not only virus, but products derived from the host; and the possible effects of the latter cannot be neglected. The assumption that the result obtained by the injection of virus-containing material into a susceptible animal is determined by the virus alone is, as we shall see, quite unjustified.

Such knowledge as we have has been gained mainly by experiments on normal animals. So far as it goes it suggests that the immediate clearing mechanism involved in freeing the blood stream and tissue fluids from virus is the same as that brought into play in the case of bacteria, and that, in a naturally immune animal, or in a relatively susceptible animal injected by a route that does not allow the virus to gain easy access to the tissues for which it has a special affinity, this clearing mechanism is capable of functioning very effectively.

Thus Gins and Weber (1916) found, in conformity with the results of earlier workers, that vaccinia virus of ordinary potency disappeared rapidly from the blood stream after intravenous injection. When large amounts of virus were injected, and the organs were tested within 5 hours, virus could usually be recovered from the spleen, less frequently from the liver, but never from the bone-marrow. Douglas, Smith and Price (1929)—who were, it will be remembered, working with a highly potent strain of virus—record four experiments in which various organs were tested for virus within a few days after an intravenous injection. In these the virus was recovered in each case from lungs and spleen, in 3 of 4 cases from the liver, and in 3 of 4 cases from the bone-marrow; but the fact that infection was in all cases widely generalized makes the significance of these findings doubtful. Of more interest are the relative frequencies of vaccinial lesions in the different organs and tissues. Of 36 rabbits injected intravenously the numbers showing lesions at different sites were as follows: skin 31, mucosa of lips or nose 26, tongue 24, lungs 35, liver 24, spleen 24, adrenals 14, œsophagus 1, bladder 1, intestine 1, muscles 2, heart 1, pericardium 1, peritoneum 3. Lesions were also relatively frequent in the testes among the males, and in the ovaries among the females. Thus we find the highest frequencies in those tissues for which vaccinia virus is known to have a special affinity and in those organs—lungs, liver, spleen and adrenals—which are primarily concerned in freeing the blood stream from inanimate foreign particles or from bacteria.

Flexner and Amoss (1914) record that the injection of poliomyelitis virus into the veins of monkeys—a route that does not commonly lead to the production of the typical disease—is followed by the prompt deposition of the virus in the spleen and bone-marrow, but not in the kidneys. Galloway (Report 1931) has recorded a few experiments in which the infectivity of various organs was determined 24–48 hours after the injection of foot-

and-mouth virus into the pad of the guinea-pig's foot. The concentration of virus was highest in the blood, but the spleen, liver and lungs contained virus in detectable amount, while the mesenteric glands, ovary, testis and muscles did not. In dog distemper (Laidlaw and Dunkin 1928*a*, *b*), organs rich in reticulo-endothelial cells, such as the spleen, show a high virus content.

A review of the available data appears to justify the following conclusions. Where the virus concerned has an affinity for some special tissue in which it causes its characteristic lesions, it will, naturally enough, be found in the greatest concentration in those lesions or in their immediate neighbourhood. Thus we find vaccinia virus in the highest concentration in the lymph of the pustules, the virus of foot-and-mouth disease in the fluid of the vesicles, the virus of rabies, or of poliomyelitis, or of Borna disease, in the central nervous system, and so on; but even in these diseases the other tissues in which the virus is most frequently present, if we except the blood, are those concerned in the normal clearing mechanism—the spleen, liver, lungs, bone-marrow or adrenals. In generalized infections, in which localization in the skin or nervous system is not a feature of the disease, the reticulo-endothelial tissues frequently show the highest virus content.

The blood we must consider in rather more detail. That the virus may often be demonstrated in blood withdrawn during the febrile stage of illness, or even at other times, we have already seen; but many of the results recorded, particularly in the later stages of experimental infections, have been curiously irregular. It would appear that these irregularities have been due in part to the fact that the virus is often present in the cellular elements—particularly in the leucocytes—rather than in the plasma, and that viricidal antibodies may appear in the plasma, while virus is present in the cells.

As long ago as 1899 Kolle showed that the infective agent in the citrated blood of an animal suffering from cattle plague was readily removed by centrifugation. The supernatant plasma was non-infective; the deposit, containing the blood cells, infective to a high degree. Todd and White (1914) studied this phenomenon in greater detail and showed that the virus was mainly associated with the leucocytes, and Schein (1917) and Daubney (1928) recorded similar findings. Russ (1906) (see also Landsteiner and Russ 1906) found that the virus of fowl plague was present in greater amount in the cellular constituents of the blood than in the plasma, and Todd (1928*a*) has shown that the concentration is highest in the leucocytic layer, though Doerr and Gold (1932) record experiments which they interpret as indicating an adsorption of the virus by the red cells.

Smith (1929) has studied this problem in some detail in experimental vaccinia in the rabbit. Comparing the infectivity of the whole blood, the plasma, and the washed deposit of cells during the early days of a generalized infection he found that the washed cells were most infective, and the plasma non-infective. By fractional centrifugation it was possible to show that the red cells played no part in fixing the virus. The results suggested strongly that the leucocytes alone were concerned, but the possible participation of the blood platelets could not be entirely excluded. At a later stage—and this is the immediately significant point—the washed cells might be infective while neither the whole blood nor the plasma produced any lesion in susceptible rabbits. After intradermal inoculation of virus the washed cells might be found infective in animals whose whole blood gave consistently negative results.

In further experiments it was found that specific antibodies made their appearance in the plasma of infected rabbits as early as the 3rd day after infection and thereafter rapidly increased in concentration. There was, therefore, a period during which the leucocytes contained active virus while the plasma contained protective antibodies. Infectivity tests carried out with the whole blood during this period gave irregular and

often negative results, depending on the balance between virus and antibody. But if washed cells, freed from antibody, were used for the test inoculation, virus could regularly be demonstrated in the blood up to the 8th day after infection. Berry and Kitchen (see Russell 1932) in a case of yellow fever noted the simultaneous presence of virus and protective antibodies in the blood on the 4th and 5th days of disease. Such observations indicate clearly that caution should be exercised in assuming that any tissue extract or body fluid is necessarily free from living virus because it is non-infective.

The data that enable us to compare the fate of a virus when injected into an immunized animal with its fate when injected into a normal animal of the same species are even more scanty. There is the clear and significant fact that the characteristic signs of infection do not occur, or are very greatly modified; but beyond that fact we know relatively little.

In the particular case of foot-and-mouth disease, Bedson, Maitland and Burbury (1927) have shown that three stages—not of course sharply demarcated from each other—can be recognized in the active immunization of the guinea-pig. In the first, the animal resists the intramuscular injection of a dose of virus that uniformly causes a generalized infection in controls, but responds to inoculation into the pad of the foot by developing a local vesicle followed by generalized lesions. In the second the solid resistance to intramuscular injection is associated with a heightened resistance to intradermal injection, so that the local vesicle is not followed by generalization. In the third and final stage the guinea-pig is immune to the inoculation of the virus by any route. There is here a clear suggestion of an improved clearing mechanism that, in the partially immunized animal, is able to protect the sensitive tissues if these have not been directly infected at the time of inoculation. Analogous observations have been made during the period of fading immunity in cattle and pigs (Andrews and others; Report 1931). Recent experiments by Galloway (Report 1931) on the survival of foot-and-mouth virus after inoculation into the tissues of immunized animals are in general accord with this view. Virus injected into the mucous membrane of the tongue of immunized rabbits could not be recovered from the blood at any time from the 2nd to the 36th hour after inoculation. Similarly, virus inoculated into the tongue or pads of immunized guinea-pigs could never be recovered from the blood. It could be recovered from the local lesions from 30 minutes to 24 hours after injection, but not after 36 hours.

Of particular interest is an isolated experiment recorded by Smith (1929). Vaccinia virus was injected intravenously into an immunized rabbit, and the washed blood cells were tested for infectivity after 30 minutes, 1, 2, 4, 6 and 8 hours. The cells were infective up to and including the 4th hour, after which they were non-infective. This rapid disappearance of virus from the blood of an immunized animal contrasts sharply with the course of events in a normal rabbit.

The relative parts played by cells and by humoral antibodies in immunity to virus diseases form a subject on which opinion is still sharply divided. It must be understood that, when we use the term "cells" in relation to viruses, we are generally referring not to the reticulo-endothelial cells of the body, which are so active in antibacterial immunity, but to the particular cells invaded by the virus. The reticulo-endothelial system, as we have just seen, undoubtedly acts in conjunction with neutralizing antibodies to dispose of certain types of virus; but when we speak of cellular immunity in virus diseases we have in mind an entirely different mechanism, namely the resistance of normally susceptible cells to invasion by active virus particles. We know that neutralizing antibodies, if mixed with virus before inoculation, or if injected into an animal before the virus, are capable under suitable conditions of preventing infection. Not all virus diseases

can be protected against in this way. In some diseases, for example, such as psittacosis and lymphocytic choriomeningitis, potent neutralizing antisera are difficult to prepare. In others, such as poliomyelitis, though neutralization of virus *in vitro* is possible, injection of serum into a monkey or a cotton rat before inoculation with the virus has no protective effect. The reason for this is probably twofold. Firstly, the virus gains access to the nervous system from the site of injection without entering the blood stream; and, secondly, the cerebrospinal fluid, which is the only fluid in contact with the nerve cells of the brain and cord, does not contain the blood globulins, since the choroid plexus is impermeable to the large molecules of these substances (Perdrau 1938). Moreover, as has already been pointed out, even in virus infections in which a strong neutralizing antibody can be obtained and in which the virus is not essentially neurotropic, the available evidence suggests that inactivation of the virus can occur only extracellularly. Once the virus has penetrated the cell, it seems to be adequately shielded from the antibody. If, as in the prophylaxis of measles, the antibody reaches the majority of the susceptible cells before the virus, the virus may be neutralized either on the surface of the cell or in its immediate vicinity; but if the serum is given too late, after the virus has penetrated the cells, it is almost or completely without effect.

The protective effect of the cell on viruses was studied by Perdrau and Todd (1936). They found that in suspensions free from living animal cells the viruses of fowl plague, herpes, vaccinia, and louping-ill were easily destroyed by photodynamic action (see Chapter 5). But in freshly prepared suspensions of living cells from infected animals they proved very much more resistant. This was not due simply to the presence of the cells, since it was shown that the increased resistance of the viruses did not become apparent for some time after the inoculation of the virus into the animal. Fowl plague virus, for example, inoculated intracerebrally into a fowl, remained susceptible for an hour; vaccinia virus inoculated intratesticularly into a rabbit remained susceptible for about 10 hours; and herpes virus inoculated by the same route remained susceptible for 18 hours. The latent period elapsing before the virus became resistant was interpreted as a measure of the time required by the virus to penetrate the cell and thus obtain protection from the lethal action of the dye. It may be noted that protection was very difficult to establish when the virus was mixed with cell suspensions *in vitro*, unless growing tissues, such as those of the chick embryo, were used. This suggests that penetration of the virus occurs most readily in cells which are either growing or actually dividing.

We see, therefore, that in some diseases in which a second attack is known to be very uncommon neutralizing antibodies appear to play little or no part in the development or maintenance of immunity. Are we justified in assuming that in these instances immunity is purely cellular? This is a difficult question to answer. As Bedson (1937) points out, the mere inability to demonstrate circulating antibody is not sufficient reason for postulating a tissue immunity. It has been abundantly demonstrated that in many virus diseases it is possible to protect a susceptible animal with a dose of serum so small as to render detection of antibody in the circulation highly problematical. It is legitimate to assume, therefore, that, even in the absence of demonstrable circulating antibody, a true humoral immunity may exist due to the inactivating effect on the virus of neutralizing antibody distributed around or on the surface of the susceptible cells. Nor are we justified in concluding that humoral immunity may be ruled out, because no quantitative relationship appears to exist between the amount of circulating antibody and the degree of immunity.

Webster (1938), for example, found that susceptible mice, inoculated subcutaneously or intraperitoneally with 15,000 intracerebral lethal doses of St. Louis encephalitis virus, developed an immunity in 4–7 days to the intracerebral or intranasal inoculation of 1,000 to 1,000,000 lethal doses of virus. The immunity lasted for 4–6 weeks, then declined gradually till it disappeared after 8–12 weeks. While immunity was at a maximum, circulating antibodies were not detectable, though they appeared later when immunity was declining. Webster therefore regards this as an instance of tissue immunity in the absence of humoral immunity. Though this is perhaps the obvious interpretation, it is difficult to accept it without reserve, since we know too little about the distribution of the antibody in the tissues. It may be, as Bedson (1937) suggests in respect of poliomyelitis, that the antibody which appears in the circulation is a response to virus in tissues other than the central nervous system and bears little relation to that in the nervous tissue itself.

Nevertheless, in diseases due to the more strictly neurotropic viruses, of which rabies and poliomyelitis may be quoted as examples, there is so far little or no evidence to suggest that immunity is in any way dependent on the action of humoral antibodies. One attack of the disease appears to confer an almost, though not quite, absolute protection against a second attack, but the mechanism by which this end is achieved is open to doubt. One interesting observation that may throw light on it is the so-called *interference phenomenon*, described by Hoskins (1935) and studied further by Findlay and MacCallum (1937).* It was found that monkeys inoculated with a pantropic strain of yellow fever virus died; but that if neurotropic virus, which is not normally fatal, was injected at the same time, the animals survived. Since the precocious development of antibodies seemed to be ruled out, the explanation offered is that the neurotropic variant occupied a proportion of the cells that would normally have been invaded by the pantropic virus and so prevented them from being infected by this fatal form of the virus. Immunity of this type, in which a cell already occupied by a virus, is resistant to infection by other particles of the same or nearly related virus, may perhaps be referred to as *pre-emptive immunity*—a term suggested by Dr. C. H. Andrewes. We know that such an immunity occurs in plants, in which humoral antibodies have never yet been demonstrated; and there is increasing evidence that it plays a part in the defence of the host against some of the animal virus infections. If this conception is ultimately proved to be correct, then the existence of a true cellular immunity will have been established. At present we must regard it as no more than a plausible guess.

It may be noted that an apparently similar phenomenon has been observed by Delbrück and Luria (1942) in a study of two strains of bacteriophage, α and γ, active against *Bact. coli*. It was found that when sensitive bacteria were exposed simultaneously to the action of both bacteriophages, the γ-phage completely suppressed the growth of the α-phage. It is suggested that, for the multiplication of bacteriophage within the cell a key-enzyme activating the necessary substrate is required, and that for some reason one strain of bacteriophage is more successful than another in competing for this enzyme. It was further shown by Luria and Delbrück (1942) that the interfering action of the γ-phage, though destroyed by heat, was resistant to mild doses of ultra-violet rays sufficient to prevent active growth of the phage itself. The irradiated phage did not lyse the bacteria to which it became attached, but it did prevent their multiplication. These observations are of great interest, and point the way towards the possible use of ultra-violet irradiated vaccines in the prevention of virus diseases.

The Nature and Reactions of the Antiviral Antibodies.

In discussing the rôle of the serum antibodies in antibacterial immunity, we were able to draw on our extensive knowledge of the ways in which antibodies and bacteria react *in vitro*. Our knowledge of the *in vitro* reactions of filtrable viruses and their specific antisera is as yet rudimentary; but it will help us in the present discussion if we summarize the scanty evidence available, comparing it with that set out in Chapter 7.

In the particular case of vaccinia virus, it has been shown that the serum of an immunized rabbit reacts *in vitro* with virus-containing material from the pocks of variola or vaccinia in man, giving complement fixation and, under suitable conditions, visible precipitation (Gordon 1925, Burgess, Craigie and Tulloch 1929, Bedson and Bland 1929, Craigie and Tulloch 1931, Havens and Mayfield 1931). These reactions are specific—suspensions of material from the lesions of chickenpox do not react with anti-vaccinial sera—and they confirm the antigenic similarity or identity of the viruses of vaccinia and variola. It will be noted that the antigenic material employed is extremely crude. Vaccine lymph contains substances derived from the tissues of the calf and a number of non-pathogenic contaminating bacteria as well as the vaccinia virus itself, and antigenic substances of similar kinds are present in material derived from human skin lesions.

It has been suggested that the reactions referred to above may be due to foreign contaminating bacterial antigens rather than to antigens derived from the virus; but this criticism has been adequately met.

Bedson and Bland (1929) showed that antivaccinial sera did not fix complement in the presence of bacteria derived from calf-lymph, nor did antisera prepared against those bacteria fix complement in the presence of the lymph (see also Havens and Mayfield 1931). Craigie and Tulloch (1931) record the failure of antisera prepared against the secondary bacterial infectors, found in vaccinia and variola crusts, to give visible flocculation with crust extracts. They note, moreover, that antisera prepared by injecting rabbits with extracts of the bacteriologically sterile organs of an animal suffering from generalized experimental vaccinia give good flocculation with crust extracts, and that antisera prepared against dermal vaccine lymph give good flocculation with extracts of virus-containing organs. Similar observations have been recorded by Thompson, Hazen and Buchbinder (1932). The conclusion that these reactions depend on antigens present in or derived from the virus itself is confirmed by the observation of Gilmore (1931) that antivaccinial sera prepared in the rabbit, or human serum derived from cases of variola minor, give specific complement fixation in the presence of vaccinia virus which has been propagated through 17 to 24 successive subcultures in an appropriate tissue medium.

Observations by Ledingham (1931) and by other workers have an important bearing on this problem. The tissues of animals infected with vaccinia may be shown by appropriate staining methods to contain minute granules, the Paschen bodies, which almost certainly represent the actual virus—such bodies may be demonstrated in this and other virus diseases as optically resolved images by the beautiful methods devised by Barnard (1919, 1926, 1932, Barnard and Elford 1931–32). By differential centrifugation Ledingham has been able to prepare suspensions of these elementary bodies almost entirely freed from extraneous material, and finds that, in this state, they are specifically agglutinated by an antivaccinial serum.

Craigie (1932) has recorded experiments which indicate that the flocculation that occurs in a mixture of vaccinia virus and antivaccinial serum is not wholly, or even mainly, an agglutination reaction; but is due in large part to the interaction of a soluble specific

substance derived from the virus with a corresponding antibody in the serum. In the precipitate so formed the virus particles are entangled. The virus particles separated from the soluble substance are agglutinable by the serum, and absorption experiments suggest that the precipitation and agglutination reactions are dependent upon the same antigenic components. Further observations by Craigie, Shedlovsky, Smadel and others (see Chapter 41) have now shown the existence of a soluble, so-called LS, antigen, containing heat-labile and heat-stable components, which reacts with specific antibody in complement-fixation and precipitation tests, but which apparently plays no part in the reaction with neutralizing antibody.

Smith (1932) has recorded experiments that indicate the close similarity between the filtrable substance described by Craigie and the bacterial haptens described in Chapter 7. Rabbits were injected intratesticularly with vaccinia virus, and autolysates were prepared from the infected testicular tissue. From these autolysates a soluble specific substance was obtained, which would withstand boiling, but not autoclaving. It gave a positive biuret test, positive reactions for arginine and tyrosine, negative reactions for tryptophan and cystine, and a positive Molisch test for carbohydrate. It therefore contains both protein and carbohydrate radicles. It shares with the bacterial haptens the capacity to give specific precipitation *in vitro*, and the incapacity to stimulate antibody production *in vivo*.

Douglas and Smith (1930) have studied the action of whole blood and of serum-leucocyte mixtures on vaccinia virus. They find that leucocytes take up the virus *in vitro*; that immune is significantly more viricidal than normal blood; and that normal cells in the presence of immune plasma appear to be more viricidal than immune cells in the presence of normal plasma.

It happens that the greater part of the available data with regard to the *in vitro* antigen-antibody reactions of the filtrable viruses refers to the particular case of vaccinia; but we shall probably not err in regarding this as an illustrative example of the behaviour of viruses in general. All the evidence that we have points in this direction.

Thus Bedson and Bland (1929) have demonstrated specific complement fixation with herpes virus and an antiherpes serum, Ciuca (1929) with foot-and-mouth virus and the corresponding antiserum, Frobisher (1929) with yellow-fever virus and the sera of convalescent men and monkeys, Laidlaw and Dunkin (1931) with the virus of dog distemper, and Broom and Findlay (1932) with the virus of Rift Valley fever and the sera of men, monkeys, sheep, rats and mice that have recovered from natural or experimental infection. Ledingham (1931) has demonstrated the agglutination of suspensions of the Borrel bodies of fowl-pox by the sera of fowls that have recovered from that infection, and Bedson (1932) has demonstrated agglutination and complement-fixation reactions between the elementary bodies of psittacosis virus and a specific antiserum.

It would seem, then, safe to conclude that naturally infected men and experimentally infected animals produce specific antibodies to a filtrable virus, which react with that virus *in vitro* in the same specific way as an antibacterial serum reacts with the homologous bacterium, or with its products, though there is reason to believe that the antigen responsible for the *in vitro* agglutination, precipitation and complement-fixation tests may be different from that which combines with neutralizing antibody.

Certain observations on the neutralization of a filtrable virus by an antiviral serum—as studied by inoculation tests in susceptible animals—have raised doubts as to whether the antigen-antibody reaction involved is entirely similar to that which occurs between a bacterium and the corresponding sensitizing antibody.

Andrewes (1928*b*) found that mixtures of vaccinia virus with antivaccinial serum might fail to give rise to lesions when injected intradermally, indicating effective neutralization, though they proved infective when injected intratesticularly, intracerebrally or intravenously. He found also that virus could be recovered from a neutral serum-virus mixture for periods as long as 24 hours by simple dilution, and that the specific neutralizing

antibodies could be recovered from the mixture by filtration through a candle that held back the virus. Todd (1928c) found that mixtures of fowl-plague virus and anti-fowl-plague serum, which were just neutral when undiluted, regained their infectivity on tenfold dilution with saline. This *dilution phenomenon* was observable after 4 hours' contact between virus and serum at 37° C., but not after 24 hours' contact at 28° C. The effect of dilution at the earlier period was also evidenced by the fact that a mixture that was inactive when injected intramuscularly was infective when injected intravenously. Bedson (1928) records similar experiments with herpes virus and an antiherpes serum, and concludes that there is a slow union between the virus and the viricidal antibodies *in vitro*, the effect of dilution being limited to the period during which this union is incomplete. In later experiments (Bedson 1929) he demonstrated that collodion particles would adsorb the specific antibodies from an antiherpes serum, and that particles so treated would adsorb herpes virus more readily than untreated particles, or than particles treated with normal serum. From this he concluded that the antigen must have united with the antibody. Andrewes (1930) re-examining the reaction between vaccinia virus and an antivaccinial serum in the light of these results found that it became less and less easy to recover active virus from serum-virus mixtures as the period of contact was prolonged, but that the time required for complete irreversible inactivation of the virus was of the order of 24 to 48 hours at 37° C., or 4 to 8 days at room temperature. Similar observations have been made by Shaffer and Enders (1939) and Burnet and Lush (1939*b*) on the herpes virus. The observation of Smith (1930) that it is possible by the use of optimal amounts of absorbing material to absorb separately the antibodies acting on herpes and vaccinia virus from a mixture of antiherpes and antivaccinial serum indicates quite clearly that, under suitable conditions, an effective antigen-antibody union occurs; though Sabin (1935) records experiments from which he draws quite different conclusions.

It would seem probable that antibodies acting on the filtrable viruses form with them a union which is at first of a loose kind, easily dissociable on simple dilution, and which attains stability and firmness only after the lapse of a considerable period of time, probably as the result of some secondary change in the antigen-antibody complex. Closely analogous relations have been shown to hold between certain bacterial antigens and their antisera.

On the other hand, differences from these antibodies have been noted.

For example, in the neutralization of bacteriophage by antiserum, Andrewes and Elford (1933) found that within limits the percentage reduction in the number of active particles was independent of the concentration of bacteriophage in the mixture. Keogh (1936), working with chorio-allantoic membrane cultures, has recorded similar findings in vaccinia. Thus, in one experiment, a 1 : 10 dilution of immune serum, when mixed in equal quantity with a virus suspension, produced a 99·3–99·5 per cent. reduction in the expected number of pocks, irrespective of whether the virus suspension was diluted 1 : 30, 1 : 90, 1 : 270, or 1 : 810. This *percentage law* is supposed to result from the circumstance that within a certain range of dilutions the virus particles are so widely separated that they do not compete with each other for the antibody molecules. A further similarity to phage-antiphage serum reactions was observed in the percentage neutralization of vaccinia virus. Neutralization in constant proportions did not occur. For instance, with one serum studied the pure serum inactivated 99·6 per cent. of virus, a 1 : 10 dilution 99·4 per cent., a 1 : 100 dilution 97 per cent., and a 1 : 1,000 dilution 80 per cent. (See also Chapter 11.)

How neutralizing antibodies act is still subject to discussion.

From the work of Salaman (1937) it seems clear that the neutralizing antibody to vaccinia becomes fixed to the virus particles themselves. Absorption with elementary bodies, but not with the soluble specific substance that takes part in the complement-fixation and precipitation tests, removed the virus-neutralizing bodies from a serum.

The observations recorded above suggest that the neutralizing antibody does not lead directly to the death of the virus; and the finding of virus and antibody together in the circulating blood or in growing tissue cultures in vaccinia (Smith 1929), ectromelia (Downie and McGaughey 1935), and psittacosis (Bedson 1937) is additional evidence in favour of this view. The experiments of Andrewes (1929*a*, *b*) on Virus III and of Rivers, Haagen and Muckenfuss (1929*a*, *b*) on vaccinia and herpes show that in tissue cultures the formation of characteristic inclusion bodies can be prevented by the addition of immune serum to the cultures before the virus. This may be interpreted as meaning that the antibody interferes with the penetration of the cell by the virus, or that it so alters the virus as to prevent its multiplication when it reaches the interior of the cell. Whichever explanation is correct, it is known that the inactivating effect of antibody is increased by the presence of leucocytes, suggesting that, as with bacteria, one of the main functions of neutralizing substances in the serum is to prepare the parasite for phagocytosis and subsequent intracellular destruction.

As is the case with the antibodies acting on bacteria and their products, the antibodies in antiviral sera appear to be confined to the globulin fractions.

Hartley (1914) concluded from the results obtained in the fractional precipitation of anti-cattle-plague serum that the antibodies were contained in the euglobulin. Maitland and Burbury (1927) found that the antibodies in the serum of guinea-pigs immunized against foot-and-mouth virus were associated with the serum globulin. Weyer, Park and Banzhaf (1929) concluded that the antibody of poliomyelitis antiserum was contained in the pseudoglobulin, while Morgan and Fairbrother (1930) found the euglobulin the most potent. Henseval (1919) found the antibodies of a vaccinial antiserum to be distributed throughout the serum proteins, but describes the euglobulin fraction as especially potent. Ledingham, Morgan and Petrie (1931) found antibody in both the euglobulin and pseudoglobulin fractions of an antivaccinial horse serum; the highest concentration was in the euglobulin, but the greatest absolute amount was in the large pseudoglobulin fraction. Laidlaw and Dunkin (1931) found the antibody of distemper antiserum to be confined to the globulin fraction; further study showed that the antibody was associated with a globulin fraction that was insoluble in water, but soluble in weak acids or alkalies and in water saturated with CO_2, thus behaving like the pneumococcal antibody described by Felton (1925, 1926, 1928).

The Antigenic Structure of the Viruses.

The antigenic structure of the viruses has already been discussed in Chapter 41, and we need do no more here than draw attention to the effect of antigenic variation on the degree of resulting immunity.

Just as there are different serological types of pneumococci, each type acting specifically so far as its more important immunity reactions are concerned, so different types of certain viruses are known which seem to behave in an analogous manner. At least three types of foot-and-mouth virus have been recognized, each of which produces the same clinical syndrome in susceptible animals but gives rise to immunity only against itself. Several immunologically distinct types of the poliomyelitis virus have been demonstrated, which are so sharply defined that the serum of monkeys convalescent from one type will not protect against another, and convalescent monkeys immune to re-inoculation with the homologous type can be re-infected with a heterologous type. Other viruses in which antigenic variants occur are those of vesicular stomatitis, African horse sickness, influenza, and the encephalitis group of viruses.

It is clear that the occurrence of multiple serological types should make us very cautious in accepting statements on the effectiveness of the immunity that follows a single attack of a particular virus disease. One attack of foot-and-mouth disease

does not always protect against a second, because the causal viruses in foot-and-mouth disease are not immunologically identical. The occasional second attacks of poliomyelitis that have been recorded (for references see Flexner 1937, Howe and Bodian 1941) may well have been due to infection with a type of virus different from that responsible for the first attack. In influenza the transitory nature of the immunity is probably due to a different cause, since persons convalescent from infection with one type may be re-infected with the same type a few months later (Francis *et al.* 1944); though this does not make it less desirable to pay attention to the infecting type in the vaccine prophylaxis of any given outbreak of the disease.

Allergy in Virus Diseases.

The characteristic response to reinoculation with vaccinia virus affords one of the classical examples of an allergic reaction. The typical sequence of events after a successful primary inoculation commences with an incubation period lasting about 3 days, followed by the appearance of papules at the sites of inoculation on about the 4th day. These develop into compound vesicles during the next 5 days, become definitely pustular about the 10th day, and heal by the well-known scabbing process between the 14th and 21st days. If a person who has been successfully vaccinated is again injected with calf lymph during the period of waning immunity, but before he has again become fully susceptible, the most noticeable feature in the local reaction is an acceleration of all stages. The papules appear earlier, sometimes within 24 hours; and vesiculation and pustulation, when they occur, are in evidence at a far earlier period than after primary vaccination. Very frequently, however, the reaction ceases at the papular stage, and this may be so transitory as to be missed unless daily examinations are made. In any case, the induration round the papules or vesicles is usually far less marked after a secondary than after a primary vaccination, and the constitutional symptoms are slighter. We have, in fact, the typical allergic combination of accelerated response with localization of infection. It would appear (Andervont and Rosenau 1930) that vaccinia virus killed by heating to high temperatures is capable of producing the characteristic immediate reaction with papule formation in persons previously vaccinated; while it has no effect in unvaccinated persons, nor does it produce an active immunity. There are, of course, many analogous observations in the case of bacterial allergy and hypersensitiveness.

There is no reason to believe that other virus infections differ from vaccinia in their ability to induce the allergic state, though this aspect of antiviral immunity has not yet been studied in any detail. A few observations are on record. Thus, Andrewes (1928*a*) records an allergic reaction in rabbits infected with Virus III. Animals that had been solidly immunized showed a relatively small local lesion when reinoculated in the testes, but no nuclear inclusions were present in these lesions. Partially immunized rabbits developed more pronounced testicular lesions, as judged histologically, than did either normal or solidly immunized animals. These lesions, however, unlike those produced in normal rabbits, were usually free from nuclear inclusion bodies.

Other Factors in Virus Infections.

Our knowledge of the interplay of factors other than those we have referred to above is very scanty; but so far as it goes it suggests no fundamental differences between the mechanisms involved in antiviral and antibacterial immunity.

We have seen that the reticulo-endothelial cells are intimately concerned in the pathogenesis of the virus infections, and it seems altogether probable that they play an important

rôle in the production of antiviral antibodies. The time relations of the antibody response to virus infections would seem to be of the same general type as those that occur in bacterial infections, or in active immunization against a bacterial antigen (see Ciuca 1929, Ledingham 1932).

It will be remembered (Chapter 44) that Duran-Reynals (1929) described the enhancement by testicular extract of the skin lesions produced by vaccinia virus in the rabbit—a phenomenon which McClean (1930) showed to be due to a "spreading factor," later identified as hyaluronidase. There is, however, no evidence that the viruses resemble some of the bacteria in producing this substance; so that as far as natural infections are concerned the importance of hyaluronidase would appear to be limited to the theoretical possibility of a mixed infection by a virus and a hyaluronidase-producing bacterium.

A series of observations by M. Maitland (see Report 1928) on the factors determining the localization of the virus in experimental foot-and-mouth disease in the guinea-pig are of considerable interest. Seeking an explanation of the limitation of the vesicles to the mouth and the hairless part of the feet, she transferred strips of hairy skin to the soles of guinea-pigs' feet and found that vesicles developed in the hairy skin so transferred, whether the virus was injected directly into it or introduced elsewhere in the body. She also showed that, when virus was inoculated intramuscularly, vesicles failed to appear on the sole of one hind foot, if that foot was protected by cotton-wool and a bandage. On the unprotected feet vesicles appeared as usual. Again, when the bottom of the cage was made of wire mesh, the pressure on the toes and anterior part of the feet resulted in the appearance of vesicles on these parts, though they are not the usual sites of vesicle formation.

It may perhaps be noted that transmission of virus diseases from the mother to the fœtus or to the new-born child is believed to be very uncommon. According to Levine, Bullowa and Scheinblum (1943), who have summarized the evidence, a few cases of infection *in utero* with varicella, measles, and smallpox have been recorded. Goodpasture (1942) has shown that the placental membrane is impermeable to a number of viruses. On the other hand, specific antibodies are known to reach the human fœtus. This was first demonstrated by Fildes (1915) for syphilitic immune bodies, and has subsequently been proved to hold true for virus diseases such as measles, chicken-pox, poliomyelitis, and influenza (for references, see Levine *et al.* 1943).

Useful reviews, which have been freely drawn on in the writing of this chapter, have been published by Bedson (1937), Burnet, Keogh and Lush (1937), Andrewes (1939), and Rivers (1943).

SUMMARY

It is perhaps a fair summary of the evidence presented in this chapter to suggest that it is compatible with the view that there is no essential difference between the mechanisms involved in antiviral and antibacterial immunity. In so far as immunity to virus infections is more effective than immunity to bacterial invasion, it seems possible that the difference is due rather to the greater limitations imposed on the virus by its habit of intracellular parasitism than to any special reaction on the part of the host.

CHAPTER 56

HERD INFECTION AND HERD IMMUNITY

In the preceding chapters we have taken as our host unit the individual man or animal. It is clearly possible to work with a different unit—the herd. If we wish to study the epidemic spread of infection, and the factors that favour or prevent it, then it is with this larger unit that we must deal.

The herd, like each of its members, has a characteristic structure; and this structure, from our present point of view, includes not only the hosts belonging to the herd species, and their spatial relationships to one another, but the presence and distribution of alternative animal hosts and possible insect vectors of infection, as well as all those environmental factors that favour or inhibit the spread of infection from host to host. This herd structure, apart altogether from the susceptibility or resistance of the individual hosts, may play a decisive part in the immunity of the herd as such. A herd may be immune to a particular disease—in the logical sense that it will resist the introduction of infection from without—although each of its members is fully susceptible, and would fall an easy victim if he strayed to a herd with a structure that allowed an endemic prevalence of the disease in question. In this sense the English herd is immune to plague; because the association of man, the rat and the flea is not now of a kind to allow spread along natural routes. It is probably immune to cholera, as the result of an adequate system of water purification. It is *not*—nor does it seem likely to become—immune to any of those diseases that are spread by droplet infection. It would take us altogether beyond our present scope to consider the known or problematical effects on herd resistance of such changes in environmental conditions; but we may at least note that many of the most striking successes of preventive medicine have been attained by altering herd structure without inducing any increased resistance in its individual members. By attacking insect vectors of infection, such as the mosquito, by preventing the frequent passage of bacteria from one person's intestine to another person's mouth by way of water and food, and by a general improvement in environmental conditions, we have succeeded in eliminating, or reducing to negligible proportions, diseases that formerly took a heavy toll of lives, and still take that toll in areas where such measures are not applied.

The type of herd immunity with which we are here concerned is that in which this freedom from the spread of infection has not yet been attained, so that contact with the bacterial parasite is at least an occasional event in the normal experience of the host species. Under such conditions the course of events in any infected herd will be determined mainly by the distribution of the parasite and the distribution of those kinds of specific immunity that we have considered in earlier chapters. Intelligent interference with the course of events is impossible without a clear idea as to what is actually happening.

We may recognize, in theory, at least six categories of hosts among any infected herd. Four of these categories include individuals who are themselves infected, (1) the typical case, (2) the atypical case, (3) the latent infection, and (4) the healthy carrier; while two categories are not themselves infected, or infective, (5) the uninfected immune and (6) the uninfected susceptible. The division between (2), (3) and (4) is formal rather than actual—these conditions shade into each other by imperceptible degrees. It is doubtful whether the division between (3) and (4) is justifiable even for convenience of description, since many, perhaps most, of the class commonly described as healthy carriers are in reality suffering from a symptomless, and often negligible, infection. It may be noted that the individuals falling in categories (3) and (4) are in general, though in a very varying degree, resistant to further infection from without; so that the only fully susceptible hosts at risk are those in class 6.

Fig. 268 may help the student to visualize the kind of distribution, both of infection and of immunity, that may be met with in infected herds under different epidemic conditions. No distinction has been made in the diagram between latent infections and healthy carriers. A few arrows have been introduced to indicate the direction of effective spread—effective in the sense of producing new cases of disease or in converting susceptibles to immunes. As we shall see, an epidemic of an infective disease is usually accompanied by an epidemic of symptomless immunization.

In this figure, A may be taken as an example of an epidemic phase in an endemic-epidemic prevalence, that is, as representing the state of affairs during an outbreak of an infective disease from which the affected herd is never completely free, epidemics of varying severity recurring at more or less frequent intervals. B may be regarded as a later stage of A, or as a small epidemic wave occurring in a herd in which susceptibles are few, while carriers are frequent. C may be taken as representing the state of affairs during a severe epidemic occurring in a herd with little initial immunity. An extreme example of this catastrophic type of prevalence has occasionally been afforded by the introduction of such a disease as measles into an isolated island community that has either never experienced the infection before, or has been free from it for many years. D may be regarded as representing a stage of relative quiescence between two outbreaks of the type depicted in A. It will be noted that the proportion of susceptibles is higher than in A or B, and with such a distribution as this a fresh outbreak of the A type is likely to occur.

As an illustration of the types of distribution depicted in A, B and D, no better example could be selected than that of diphtheria. We are here dealing with a disease that is essentially a toxæmia; and, as we have seen, an effective antitoxic immunity will in this case protect the host against clinically detectable infection In the Schick test we have a method which allows us to divide the members of any herd into susceptibles and immunes. Except in the case of very young children a negative reaction may be taken as an indication that an individual has something over 0·01 A.U. of antitoxin per ml. of circulating blood, and also that he will produce further antitoxin briskly and effectively in response to any entry of toxin into his tissues. We may, if we wish, obtain a more exact picture of the distribution of antitoxin, by collecting samples of blood and titrating them by a modified Römer technique (see Jensen 1933). By swabbing throats and noses, and testing the virulence of any morphologically typical diphtheria bacilli cultivated, we can

determine with some approach to accuracy the distribution of the parasite among the hosts at risk ; and we are thus in a position to give a description of the course

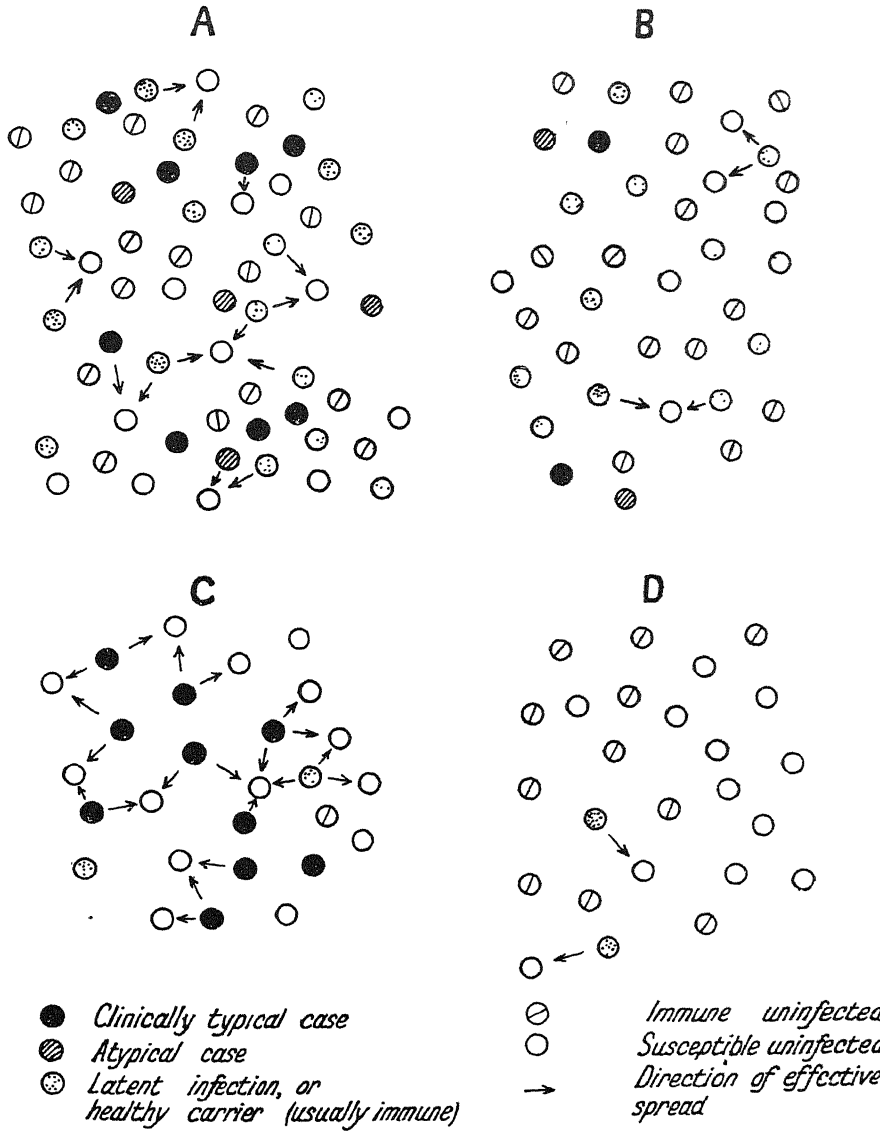

FIG. 268.

of events in any particular community that is vastly more informative than we can at the moment supply for most other diseases.

It has of course long been recognized that the diphtheria bacillus is not confined to those who are suffering from the clinical disease in its typical form. It is

frequently isolated from cases of mild sore throat associated with an epidemic of typical diphtheria, less frequently from healthy contacts, and still less frequently from non-contacts.

Kober (1899) records the isolation of diphtheria bacilli from 70 per cent. of 139 contacts who were themselves suffering from mild sore throat, and from 8 per cent. of 123 contacts who had apparently normal throats. Closeness and continuity of contact, here as in other diseases, have a considerable influence on the carrier rate. The collected figures recorded in the Medical Research Council's monograph on diphtheria (see Monograph 1923) show a 15 per cent. carrier rate of virulent diphtheria bacilli among 610 contacts in barracks or hospital wards, a 7 per cent. carrier rate among 10,883 home contacts, and a 0·6 per cent. carrier rate among the general non-contact population.

As a measure of the risk to which an ordinary urban population is submitted we may take the carrier rate of virulent diphtheria bacilli among children attending the elementary schools in and about London. During the third decade of the century it fluctuated between 2·5 per cent. and 5 per cent. (see Dudley 1923, Forbes 1927).

The events that follow the passage of virulent diphtheria bacilli from the throat of a case, or of a carrier, to the throat of a non-infected person will depend on the immunological condition of the recipient. If he is susceptible (Schick-positive) he will either respond by developing antitoxin and so becoming more resistant, and eventually Schick-negative, or else he will develop clinical diphtheria. Hence Schick-positive carriers of virulent diphtheria bacilli are very rare. They are not non-existent—they cannot be if we accept the view that the transition from the susceptible to the immune class is usually the result of latent infection—but we may take it that a person who is carrying virulent bacilli in sufficient number to be detectable by an ordinary swabbing is (*a*) immune (Schick-negative), or (*b*) undergoing rapid immunization to the Schick-negative level, or (*c*) incubating the disease.

If, then, we take the case of a relatively isolated community, such as a large boys' school, and trace the spread of infection and the development of immunity during an epidemic of diphtheria, we shall observe the following sequence of events.

At the start we may suppose that we have 50 to 70 per cent. Schick-negative immunes and 30 to 50 per cent. Schick-positive susceptibles. Among these boys there will be a certain number of carriers of virulent diphtheria bacilli, say 3 per cent.; these will be immunes.

When these bacilli spread to uninfected boys they may obtain lodgment either in a susceptible or in an immune; and, depending on the dose of bacilli transferred, the exact degree of immunity of the recipient and many other factors of which we have as yet no knowledge, they may bring about any of the following transformations.

Frequently:

(*a*) Schick-positive susceptible → case (mild or severe).
(*b*) Schick-positive susceptible → Schick-negative immune
  (*a*) without detectable carrying,
  (*b*) with detectable carrying.
(*c*) Schick-negative immune → Schick-negative immune carrier.

Very rarely:

(*d*) Schick-positive susceptible → Schick-positive carrier.
(*e*) Schick-negative immune → mild "bacteriological" case.

As an illustrative example of the findings that have actually been recorded in work of this kind, we may cite the illuminating studies of Dudley (1923, 1926, 1932) on diphtheria prevalence during a series of years in the Royal Naval School at Greenwich, a school of some 1,000 boys.

Between January and May 1919—the period at which Dudley's record starts—there were 65 cases of diphtheria. From then onwards until May 1921 there were no cases. Between May and July of that year 20 cases were recorded, and in the September-to-December term the outbreak reached epidemic proportions, with 77 cases. Between January and April 1922, 831 of the boys were Schick-tested. The results obtained are summarized in Table 84.

TABLE 84

SHOWING RELATION BETWEEN SCHICK REACTION AND PREVIOUS EXPERIENCE AMONG BOYS TESTED JANUARY TO APRIL 1922.

Previous Residence in School.	Experienced 1919 Epidemic.	Experienced 1921 Epidemic.	Per cent. Immune (Schick-negative)
None (new boys) . . .	No	No	58
6 months–2 years . . .	No	Yes	85
Over 3 years	Yes	Yes	95

The relation between experience and immunity is obvious. Moreover, the fluctuations in the immunity rate as plotted by terms of entrance were discontinuous. For entrants during the four terms September 1917 to September 1918 inclusive the percentage giving negative reactions in 1922 were 100 per cent., 92 per cent., 100 per cent. and 98 per cent. respectively. For the entrants during the period May 1919 to May 1921 inclusive the rates by terms of entrance were 82 per cent., 90 per cent., 82 per cent., 85 per cent., 83 per cent., 82 per cent. and 86 per cent. as compared with the 58 per cent. in boys joining in January 1922. It would appear that there had been two waves of immunization in the school, coinciding with the waves of clinical infection.

A sample swabbing of the school during the latter part of the 1921 epidemic showed 28 carriers of diphtheria bacilli in addition to the 77 cases. During the period January to July 1922 the carrier rate for virulent diphtheria bacilli was 2·2 per cent., during September to December of the same year it rose to 4·5 per cent., and during this period cases of diphtheria were still occurring. But immunization of susceptibles was proceeding synchronously with the spread of clinically detectable infection. Of 88 boys who had given positive reactions on first testing 24 reacted negatively when retested 3 months later. Similar findings are recorded for later years, with carrier rates of virulent diphtheria bacilli varying from 1·0 to 4·5 per cent., and with recurrent cases of diphtheria that never attained the epidemic frequency of September to December 1921. Thus of 35 Schick-positive entrants in March 1924, 13 had become negative within 4 months; and 2 years' residence in the school had increased the 58 per cent. immunity rate of the new boys entering in January 1922 to 84 per cent. It may be noted that this rapid immunization was confined to the boarders, forming the population of about 1,000 to which all the figures quoted above refer. There were at the school some 120 day boys, who did not share in the continuous exposure to risk of infection experienced by the boarders. Among these the rate of immunization was relatively slow. Over a 4-months' period only one of 24 Schick-positive day boys became Schick-negative.

The increasing ratio of carriers to cases as a herd becomes more and more immune is well illustrated by the case rates and carrier rates in one group of some 160 boys during the winter term of 1921 and the winter term of 1922.

	Case Rate.	Carrier Rate.
1921	7 per cent.	2 per cent.
1922	0·6 „ „	6 „ „

In 1921 during a severe epidemic, following on a period in which the school had been free from diphtheria for 2 years, the spread of virulent bacilli produced 3·5 cases to one carrier; in the winter of 1922 after this severe exposure, and in spite of the entrance of 43 new boys during the post-epidemic period, the spread of infection produced 10 carriers to one case.

In judging the significance of such figures we must remember that the real carrier: case rate over any considerable interval of time is always higher than that given by comparing the recorded case rate with the recorded carrier rate over that period—a point stressed by Dudley (1932). All clinical cases of diphtheria will be recorded. A case rate of 3 per cent. per annum in a particular community means that 3 persons in every hundred of those exposed to risk develop diphtheria during the year in question. But a carrier rate of 7 per cent. does not mean that 7 per cent. become carriers during the year; it means that at any one swabbing of an adequate sample 7 persons in each hundred are, on the average, found to be harbouring diphtheria bacilli. The total number of persons that become carriers during the period in which the three cases of diphtheria occur will be much higher. Thus, over one yearly period, Dudley records an average carrier rate of 6·6 per cent. with small fluctuations above or below this level; but repeated swabbing (7–8 times) of a large sample of boys showed that at least 40 per cent. were harbouring the diphtheria bacillus at one time or another during this period.

The general significance of the picture presented by such studies as these is clear enough; but we must remember that the two categories—immunes and susceptibles—that are divided from one another by simple Schick testing present a very incomplete picture of the graduations in resistance that actually exist in a herd at risk. Glenny (1925) defines five grades of immunity, which are set out in Table 85. These are, of course, not exhaustive; nor are they sharply demarcated from one another (see also Parish and Wright 1938).

TABLE 85

SHOWING VARYING GRADES OF RESISTANCE TO DIPHTHERIA. (After Glenny.)

	Group.				
	1	2	3	4	5
Schick test	−	+	+	+	+
Antitoxin in blood	> 1/30 A.U.	< 1/30 A.U.	0	0	0
Earlier stimuli	Many	Many	Many	Few	None
Response to further stimuli	Rapid	Rapid	Rapid	Slow	Very slow
Description	Immune	Immune	Potentially immune	Sub-immune	Fully susceptible

If we could elaborate our study of a population at risk by estimating at regular intervals the exact amount of antitoxin in each person's circulating blood; and if, dealing with a very large population, we could withdraw an adequate sample of persons at frequent intervals and determine the response of each Schick-positive person to small injections of toxoid, we should be able to build up a far more detailed picture of what was really happening. Adopting Glenny's classification, we should be able to detect the transformation from the fully susceptible to the sub-immune, and thence through the Schick-positive immune to the fully developed Schick-negative immune, as well as transference from the Schick-positive to the Schick-negative class.

Our rare Schick-positive carriers would be found in the immune or potentially immune sub-groups, and would rapidly pass into the Schick-negative class. We should almost certainly find that severe cases tended to arise from the fully susceptible Schick-positives, mild "bacteriological" cases from the sub-immunes or potentially immunes.

A point of great importance is the reaction of the Schick-immunes to the recep-
ɔn of virulent diphtheria bacilli. We know that they very rarely contract clinical
phtheria, and then only in a mild form. We know that many of them become
rriers. Is a point reached in natural immunization at which a person resists
rrier infection as well as infection in the clinical sense ? Can we grade our Schick-
ɪmunes as we grade our Schick-susceptibles, putting at the lower end of the scale
ɹose who have just attained to the Schick level of immunity, and at the upper end
the scale those who are so resistant that virulent diphtheria bacilli are unable
gain lodgment in their throats ? If a human herd is rendered 100 per cent.
ɔhick-negative, either by natural immunization or by prophylactic inoculation,
ill infection with the diphtheria bacillus be eliminated in the bacteriological sense,
ɾ will a freedom from clinical diphtheria be associated with a persistent carrier rate
ot much below that of the population at large, and perhaps with carrier epidemics ?
ɜ complete immunity, of the kind that would render a herd entirely free from in-
ɛction, likely to be attained by immunization of this kind, however far it is pushed ?

These questions have been answered to some extent. In America and Canada,
xtensive immunization of children has resulted in a significant reduction of clinical
liphtheria in the community treated, and in some cases the disappearance of the
lisease (see Russell 1943). The effect of immunization on the carrier rate appears
ɔ vary with the population. In small institutional communities, for example,
mmunization may be followed by a decline of clinical diphtheria and a rise in the
ɜarrier rate. In larger, more open communities, the increase in the number of
Schick-immunes is not accompanied by an increase in the carrier rate (see, for
example, Fitzgerald *et al.* 1938). These issues are fully discussed in Chapter 61,
but we may note here, that in so far as we are dealing with a purely antitoxic
immunity—and this is the case in our artificial Schick-immunes—we should not
expect freedom from the carrier state unless successful lodgment in the throat
depended on a local toxic effect. In so far as our natural Schick-immunes possess
an antibacterial as well as an antitoxic immunity we must remember that the
diphtheria bacillus is separable into many antigenically different types, though
all types produce the same toxin (Durand 1918, 1920, Havens 1920, Smith 1923,
Eagleton and Baxter 1923), so that we should expect any antibacterial immunity
to be type-specific. Moreover, it is very doubtful whether the mechanisms dis-
cussed in Chapter 47 would have any appreciable effect in preventing a localized
tonsillar infection.

Scarlet fever is another disease in which, by the aid of the Dick test and the
examination of throat swabs for hæmolytic streptococci, we can obtain information
of the same general kind as that now available in the case of diphtheria ; but we
have not yet any records comparable in detail and duration with those afforded
by Dudley's work at Greenwich. So far as our fragmentary records go they look
like pieces of a very similar picture, with one essential difference. The production
of the erythrogenic toxin forms a relatively small part of the pathogenic poten-
tialities of hæmolytic streptococci ; and an antitoxic immunity that will suffice
to prevent the occurrence of the clinical syndrome that we label scarlet fever will
not suffice to prevent the spread of tonsillitis, or of other clinically obvious strep-
tococcal infections (see Okell 1932). For effective immunity against all the clinical
manifestations of infection with hæmolytic streptococci we need an antibacterial
as well as an antitoxic immunity ; and this antibacterial immunity will almost
certainly be type-specific.

Turning to diseases in which antitoxic immunity, in the strict sense in which we are using that term, plays no apparent part, we are not in a position to give any adequate description of the course of events in a naturally infected herd. This is because we have no such simple tests as the Schick and Dick reactions by which to separate our immunes from our susceptibles. There are good reasons for believing that by an adequate survey, including a careful study of the distribution of the infecting organism and tests for the presence of specific antibodies in the blood of the hosts at risk, we could add greatly to our knowledge of what is happening during an endemic or epidemic prevalence. But we have not got that knowledge yet.

Some things we do know. We know that in certain diseases, such as cerebrospinal meningitis, the ratio of carriers to cases is very high (see for instance Glover 1918), so that it seems probable that the immunes greatly outnumber the susceptibles. The same general relationship—a widespread carrier epidemic associated with relatively few clinical cases—seems to hold in certain virus diseases, such as poliomyelitis and encephalitis lethargica.

In other diseases, such as typhoid fever, the ratio of carriers to cases is not so high (see Chapter 69). But we know that atypical cases of typhoid fever occur during an epidemic, and that many carriers of typhoid bacilli give no history of ever having suffered from a typhoid-like disease. It is a fairly safe assumption that an endemic or epidemic prevalence of typhoid fever is associated with the occurrence of sub-clinical immunizing infections. We know quite certainly that such a prevalence leaves behind it infected healthy carriers who may be a potent source of further spread.

THE EXPERIMENTAL STUDY OF HERD INFECTION AND IMMUNITY

It is clearly possible, by selecting a convenient host species and a parasite that spreads naturally among them, to submit problems of the kind we have considered above to direct experimental study—initiating an epidemic of a particular disease among our test population, and studying the reactions of new entrants, of old members of the herd, or of migrants from one herd to another, by any available means (see Greenwood *et al.* 1936). We can, under such conditions, observe the effects of any intentional interference we choose, splitting a herd into smaller units, reaggregating these units after any selected interval, varying the rate of immigration of susceptibles, actively immunizing some or all of our animals by vaccines of different kinds administered by different routes, and so on as new problems suggest themselves for attack. In this way we gain enormously in an increased control over many of our unknown variables; but we lose, in so far as we wish to argue from our experimental herds to happenings in the natural world outside our cages, by having to rely on analogies that are certainly incomplete, and may well be misleading. Because our control is still far from complete we must use large numbers of animals and make constant use of statistical methods in trying to assess the meaning of our results. We must, therefore, use a small, easily controlled and relatively inexpensive animal, and the mouse fulfils these requirements. Experiments of this kind have been carried out during a number of years, in England and in America, on mouse typhoid—caused by infection

with *Salm. typhi-murium* or less frequently with *Salm. enteritidis*—, on mouse pasteurellosis, and on a virus disease known as ectromelia. The American workers have also studied the spread of infection among rabbits and fowls housed in laboratories, or maintained as breeding stock by dealers. It will be convenient to consider the data thus obtained in direct relation to the observations on human herds, noting carefully the points at which particular caution must be exercised in applying the argument from analogy and in generalizing from an isolated experience.

Is there, in the spread of infection among mice, the same distribution of typical cases, atypical cases, latent infections and carriers, and the same natural immunization associated with natural infection, that occurs among human herds?

In the particular case of mouse typhoid—and almost certainly in other epidemic infections—it is quite certain that the great majority of the mice at risk are infected by the bacterial parasite at some period or other during a prolonged epidemic prevalence.

In a particular experiment (Topley, Ayrton and Lewis 1924) 5 mice were fed on a culture of *Salm. typhi-murium*. As soon as they were found to be excreting the bacillus in their fæces, 20 normal mice were added, and thereafter 1 normal mouse was added to the cage each day for 115 days. The fæces of every mouse were examined on 6 days a week during the course of the experiment; each mouse that died was examined bacteriologically, and at the termination of the experiment all surviving mice (55 in number) were killed, cultures were taken from their spleens, and their blood was tested for agglutinins. The existence of non-fatal, and apparently mild or trivial, infections was clearly demonstrated. Some mice that excreted *Salm. typhi-murium* on several occasions remained in apparent health during the whole period of their residence in the cage. When these were killed at the end of the experiment some gave negative spleen cultures and showed no agglutinins in their blood, others gave negative spleen cultures but possessed agglutinins, others gave positive spleen cultures with or without agglutinins in the serum. Taking, as criteria of infection, death from the infective disease, excretion of the organism in the fæces, and the isolation of the organism, or the demonstration of agglutinins, in the surviving mice, it was found that of 128 mice which had resided in the cage for periods of 14 to 115 days, 122 had become infected. Of these infected mice 46 were surviving in apparent health on the day when the experiment terminated, but 25 of them (54·3 per cent.) were found to be harbouring *Salm. typhi-murium* in their spleens. The collected figures for eleven different epidemics of mouse typhoid, lasting from 60 to 117 days, show that of 267 surviving mice 190 (71·2 per cent.) were latently infected (Topley 1926).

Similarly (Greenwood *et al.* 1936), the results obtained in experiments with the virus disease, ectromelia, indicated that some 80 per cent. of the mice entering the herd were infected with the virus within three weeks of entry.

The way in which the bacterial parasites are distributed among the hosts at risk is then of the same general kind as obtains in natural epidemics in man, differing mainly in the fact that fewer hosts escape infection. Is there any evidence that the spread of infection results in immunization as well as, or in place of, the production of overt disease? That survivors from an epidemic are, on the average, more resistant than new-comers to an infected herd is certain; for they live longer —usually much longer—when exposed to a subsequent wave of mortality (Topley 1921, Amoss 1922).

This increase in resistance with increasing herd experience under epidemic conditions can be studied in greater detail by constructing life tables for the mice

submitted to risk of infection during a long-continued prevalence of such a disease as mouse typhoid. It is convenient in calculating the expectation of life to limit it to 60 days, regarding any mouse living for longer periods as dying on the 60th day, since the use of the unlimited expectation of life gives undue weight to the relatively few mice that live for much longer periods, and also because we have a normal standard of comparison for the shorter period, but none for the latter.

Employing this value (${}_{60}E_x$) we find in a particular experiment, in which 3 normal mice were added to an infected herd each day from March 6th, 1921, to June 30th, 1923, that the limited expectation of life drops slightly (from 22·49 to 21 days) during the first week of herd life and then rises, at first slowly, but more steeply after the 15th day, until by the 33rd day it reaches the figure of 34·75 days. It fluctuates round this figure up to the 100th day of herd residence; after which the numbers of survivors are too small to give a reliable average. In general then, we may say that a mouse that has survived about 30 days' exposure to risk will live more than half as long again as a new-comer to the cage (Greenwood and Topley 1925, Greenwood *et al.* 1936).

We can ask the same question in another way, using a direct experimental comparison instead of a life table. In a particular experiment (Greenwood, Newbold, Topley and Wilson 1926) in which mouse pasteurellosis was the infection selected for study, two parallel epidemics (A and B) were initiated on November 11th, 1924, and were maintained by the addition of normal mice until December 1925. At regular intervals groups of mice that had survived for 10, 20, 30, 40, 50 days or more in Herd A were transferred to Herd B, and with them were added a numerically equal group of normal mice that had had no previous experience of pasteurellosis. Averaging the results, the figures shown in Table 86 were obtained:

TABLE 86

Length of Life in Herd A.	Expectation of Life in Herd B (${}_{60}E_x$).
Nil (normal entrants to B)	22·37 ± 0·36 days
10 days	21·34 ± 1·10 ,,
20 ,, ...	25·50 ± 1·13 ,,
30 ,, ...	32·55 ± 1·28 ,,
40–45 days	33·08 ± 1·52 ,,
50–60 ,, ...	37·39 ± 1·69 ,,

Here, again, survival through a testing period of 30 days or more added some 50 per cent. to a mouse's expectation of life under severe epidemic conditions.

But clearly we cannot, in the absence of further evidence, assume from such results that the mice have been actively immunized. We are dealing with fatal diseases, and natural selection has certainly been at work. In the mouse typhoid experiment, of every 1,000 mice living on day 0 (their day of entry to the herd) only 256 survived for 30 days. Death had by then removed some 75 per cent. of those at risk; and, if no active immunization had occurred, the surviving 25 per cent. would have a higher average resistance than new-comers to the herd, assuming only that the natural resistance of mice differs *inter se*, and that this difference plays some significant part in determining survival during the first 30 days—an assumption that may be very safely made. Webster and his colleagues (see Webster 1923*a*, *c*, *d*, 1924*a*, *b*, 1926, Pritchett 1925, 1926) consider that this natural, inborn resistance is the dominant factor in determining death or survival during an epidemic. That it plays some part there can be no reasonable doubt, but there are reasons for doubting its dominance, and for believing

that active immunization is exerting an effect similar in kind, if less in degree, to that exerted in the spread of diphtheria in man.

Thus (Greenwood *et al.* 1926, 1928, Newbold 1927), if the method of partial correlation is applied to the data for mouse typhoid and mouse pasteurellosis, and correlation coefficients are calculated for: (A) length of after-life and length of previous exposure, keeping constant the death rate during previous exposure and the death rate during after-life and (B) length of after-life and death rate during previous exposure, keeping constant the length of previous exposure and the death rate during after-life, we get the figures set out in Table 87.

TABLE 87

Coefficient.	Nature of Epidemic.		
	Pasteurellosis. (1)	Pasteurellosis. (2)	Mouse Typhoid.
A	$0{\cdot}194 \pm 0{\cdot}016$	$0{\cdot}150 \pm 0{\cdot}015$	$0{\cdot}307 \pm 0{\cdot}014$
B	$0{\cdot}029 \pm 0{\cdot}017$	$-0{\cdot}018 \pm 0{\cdot}016$	$-0{\cdot}282 \pm 0{\cdot}014$

Coefficient A is positive and significant in all cases, indicating that the longer a mouse has survived within limits under constant conditions as regards death rate, the longer it will continue to survive under continued exposure to infection. Coefficient B is insignificant in the two pasteurellosis experiments, significant but negative in the mouse typhoid experiment, indicating that, with equal lengths of exposure to risk, the survivors from a period of high mortality have no significant advantage over the survivors from a period of lower mortality. This latter finding clearly suggests that the elimination by death of the more susceptible mice is not a very important factor in raising the average resistance of the survivors, while the advantage derived from prolonged exposure at a constant death rate is compatible with the view that active immunization is important. The exact significance of these results is, however, uncertain. It is probable that some at least of the mice emerging from a period of high mortality will already be suffering from an infection which will cause their death in a few days or weeks, apart altogether from any subsequent risks, while it may be that fewer of the mice emerging from a more prolonged exposure to a lower rate of herd mortality are in this particular position.

The probability that active immunization is an important factor is, perhaps, increased by the observation that, in the transfer experiment with pasteurellosis, mice that had lived in herd A only during periods of low death rates—less than one-third the average death rate for the whole epidemic period—still showed a marked advantage over normal mice on transference to herd B. The limited expectation of life of those normal immigrants that entered herd B on the same days as these particular groups of migrants from herd A was $20{\cdot}9 \pm 0{\cdot}49$ days, for those migrants that had spent 50 days in herd A it was $34{\cdot}6 \pm 4{\cdot}10$ days.

It may be noted also that such evidence as is available (Topley, Wilson and Lewis 1925, Greenwood and Topley 1925) indicates that the increased resistance gained by survival in an infected herd, or after experimental infection by feeding or inoculation, is specific in the ordinary bacteriological sense. A mouse that has survived infection with *Salm. typhi-murium* appears to be no more resistant than normal mice to infection with *Pasteurella muriseptica*. This, of course, accords well with epidemiological experience in general, but not with the view that the determining factor in increasing the average resistance of a herd at risk is the selection by the sieve of death of those individuals possessing an innate non-specific resistance. If differences in innate resistance are of major importance it would appear that they must either be specific or must be differences of immunizability rather than of immunity.

Whether or not active immunization is the main factor that determines the increased average resistance of surviving mice, the grade of antibacterial immunity produced can excite little enthusiasm.

As stated above, the expectation of life limited to 60 days was selected in these and subsequent experiments in part because there is an available standard of reference for this period (Greenwood, Topley and Wilson 1931*b*). On October 4th, 1929, 20 normal mice were assembled in a cage of the same type as that used in all epidemic experiments. From then onwards until January 17th, 1930, daily additions of normal mice were made, and the herd was then observed until May 27th, 1930. The 329 mice of this experiment were living under exactly the same conditions as the infected herd, except that no infection was present at any time during the period of observation. Of these 329 mice 56 died. The limited expectation of life, as was to be expected, remained practically constant at all cage ages from day 0 to day 170—the last day for which figures were available. The lowest ${}_{60}E_x$ figure was 56·69 days, the highest 59·27 days. The figure rose slowly from just under 57 days on the day of entry to over 58 days on the 40th day of cage life—presumably as the animosities of first acquaintance were replaced by the toleration of later herd life and fighting grew less frequent. Thereafter it hardly varied.

Taking a figure of 58 as our normal ${}_{60}E_x$, we note that the best that natural immunization against mouse typhoid or mouse pasteurellosis can do—so long as surviving mice are exposed to a continuous risk of heavy infection—is to raise the expectation of life from a little under a half to a little over two-thirds of the normal figure. This is a very different picture from that presented by our study of diphtheria in man—even allowing for the fact that in the latter case we are dealing with a disease of relatively low fatality. Either mice differ in some fundamental way from men; or the conditions in mouse cages differ fundamentally from those in schools and institutions—an obvious possibility; or natural immunization against enteric infection or against pasteurellosis is less efficient than natural immunization against diphtheria or scarlet fever. Perhaps, though by no means certainly, this might be expanded to the conclusion that natural antitoxic immunization is much more effective than natural antibacterial immunization.

There is no known disease of mice that presents any close analogy with such toxæmic human infections as diphtheria and scarlet fever; but the description by Marchal (1930) of a natural virus disease of mice—ectromelia—that gives rise to severe and fatal epidemics under experimental conditions has afforded an opportunity for the study of natural immunization against a virus infection. The results obtained present a striking contrast to mouse typhoid or mouse pasteurellosis (Greenwood *et al.* 1936).

Adopting the same plan of starting an epidemic in a herd of mice and thereafter adding 3 mice a day, two epidemics of this disease have been observed over a period of some 18 months. Applying the ordinary life-table method it was found in one of these epidemics —the results in the other were entirely analogous—that the limited expectation of life (${}_{60}E_x$) on entry to the infected herd was 30·71 days. It fell until the 7th day when it was 25·39 days, this fall obviously depending on the average time taken to contract infection. From then onwards the ${}_{60}E_x$ value rose; but instead of reaching a maximal value in some 30 days at a figure far below the normal expectation of life it continued to rise until, on the 100th day after entry, it had reached the figure of 54·69 days, and thereafter fluctuated slightly above and below this value over a period of some 15 months. In other words, instead of experience and survival in the infected herd resulting, at the best, in an expectation of life of some two-thirds of the normal span, those mice that lived through some 3 months or more of the epidemic prevalence had an expectation of life little inferior to

the normal ${}_{60}E_x$ value of 58 days, though they continued to live in a herd in which the specific infection was causing a high and continuous death rate.

A more prolonged experience of the same epidemic prevalence has shown that waves of exceptionally high mortality occur during which many of the old survivors succumb; but this fact does not abolish the significance of the marked difference in behaviour between a bacterial and a virus infection over epidemic periods that last through a large part of the lifetime of a normal mouse. It seems fairly clear that, even under conditions of severe and continuous exposure to infection, a mouse can develop a relatively effective immunity to ectromelia.

How far may the course of events in an infected herd be modified by the artificial immunization of some or all of the hosts at risk?

We shall discuss in later chapters the evidence with regard to the efficacy of different kinds of prophylactic vaccination in human herds. So far as experimental epidemiology is concerned we can, at the moment, attempt an answer only in mouse typhoid and, with far scantier data, in ectromelia.

It is quite certain that active immunization with a killed culture of *Salm. typhi-murium* will increase the resistance of mice to that organism; and although some of the earlier observations (Loeffler 1906, Wolf 1908, Yoshida 1909, Brückner 1910, Webster 1922, Ornstein 1922, Neufeld 1924, Lange and Yoshioka 1924) suggest that the immunity obtained in this way is relatively poor and inconstant, repeated trials with considerable numbers of mice, and with carefully adjusted doses of vaccine and of living culture, indicate that a quite significant increase in resistance can regularly be obtained (Topley 1929, Topley, Wilson and Lewis 1925).

Thus, in one experiment, 50 mice were immunized by two intraperitoneal injections of 5×10^8 *Salm. typhi-murium* killed by formalin and heat. A week after the second injection these 50 immunized mice, together with 50 normal controls, were injected intraperitoneally with 1,000 living *Salm. typhi-murium*. The results are shown in Table 88 This vaccine had, therefore, produced the following effects: a proportion of the immunized mice showed a partial but ineffective immunity in that they lived on the average far longer than the controls but succumbed to the disease during the period of observation; 24 per cent. showed a more effective resistance by living in apparent health throughout the period of observation, but post-mortem examination showed that they were suffering from a latent infection; 18 per cent. appeared to have been rendered completely immune to this dose of bacteria, in that they remained in apparent health for 28 days and showed no evidence of infection when killed and examined by spleen culture. These results may be taken as representative of a considerable number of similar experiments.

TABLE 88

Vaccinated . . .	50	29	18·3 „	12

We should not perhaps expect an immunity of this order to be very effective as a prophylactic measure in herds submitted to a continuous risk of infection, and actual trial confirms our lack of faith.

An epidemic of mouse typhoid was started on January 1st, 1928, and was continued until September 17th, 1929, by the addition of 3 normal mice a day (Greenwood, Topley and Wilson 1931*a*). Every 7th day 10 additional normal mice, and several groups, each of 10 mice, that had been immunized with different vaccines were added to the cage. The results, as they concern the relative efficacy of different antigenic components, have already been noted on p. 1056. We are concerned here only with the results obtained with the most effective vaccines employed.

The limited expectation of life ($_{60}E_x$) of the normal mice on entry was 26·26 $\pm$ 0·641 days; for the four immunized groups that had received vaccines containing the smooth surface antigen the $_{60}E_x$ figures were 32·10 $\pm$ 0·432, 34·97 $\pm$ 0·845, 35·06 $\pm$ 0·845 and 33·71 $\pm$ 0·853 days respectively. Thus by active immunization with a killed vaccine an increase in average resistance was obtained of the same order as that attained naturally by normal mice after living for some 30–50 days in an infected herd under the joint influence of active immunization and mortuary selection.

After 60 days' residence in the cage the $_{60}E_x$ figures for the vaccinated and unvaccinated groups have, as we should expect, largely levelled up, though the vaccinated mice still show a slight advantage. The figure for the unvaccinated group has risen to 36·47 days, those for the vaccinated groups to 40·17, 37·39, 36·90 and 47·54 days respectively.

Very similar results were obtained in another experiment in which a comparison was made between the effect of administering a killed *Salm. typhi-murium* vaccine by the mouth, or by intraperitoneal inoculation (Greenwood, Topley and Wilson 1931*c*). A larger dose was used for *per os* than for intraperitoneal immunization ($5{,}000 \times 10^6$ as against 500×10^6 bacilli). In each case two doses of vaccine were given with a week's interval between them, and the mice were added to the infected herd 1 week after the second dose of vaccine. The experiment lasted from December 12th, 1929, to June 26th, 1930. The death rate in this epidemic was rather lower than in those referred to above, and the expectation of life of the normal mice on entry was therefore somewhat longer. The $_{60}E_x$ figures on the day of entry were as follows: normal mice 31·18 $\pm$ 1·04 days, mice vaccinated *per os* 35·30 $\pm$ 1·22 days, mice vaccinated intraperitoneally 38·19 $\pm$ 1·17 days.

The immunity to ectromelia induced by vaccinating mice with a formolized virus is far more effective than the immunity to mouse typhoid induced by vaccination with a killed suspension of *Salm. typhi-murium*. Thus, in one series of tests (Greenwood *et al.* 1936), 173 of 180 vaccinated mice survived a dose of ectromelia virus that killed all of 60 controls.

The expectations raised by these results were fulfilled, up to a point, in the single experiment in which the effect of active immunization against the virus disease has been tested under epidemic conditions (Greenwood *et al.* 1936).

For this experiment, a herd was selected in which ectromelia was actively spreading, and causing a high mortality. On 21.10.32, and on every seventh day thereafter for a period of 70 days, 30 immunized and 30 non-immunized mice were added to the herd. From 21.10.32 to 27.3.33 three additional normal mice were added daily. The experiment was terminated on 16.3.34. Taking the 300 immunized mice, the 300 normal controls added with them and the 210 normal mice added daily over the same period, the $_{60}E_x$ values for the day of entry to the herd were: immunized mice 49·1 days, normal controls added with immunized 20·8 days, normals added daily 21·4 days. This shows a very great advantage to the immunized mice, and it was maintained throughout later cage-ages until the combined effects of natural immunization and selection, which are so effective in this disease, had raised the $_{60}E_x$ of the surviving normal entrants to the same high level.

In the final stages of this epidemic there were many deaths among the artificially immunized mice, and among the naturally immunized survivors. Whether these deaths

were in all cases due to ectromelia it is very difficult to say. It will, in any case, be wise to withhold any final opinion as to the efficacy of immunization in affording permanent protection against ectromelia under these very severe conditions of exposure until further data are available.

The evidence so far recorded may conveniently be summarized in tabular form (Table 89). The ${}_{60}E_x$ figures for the surviving mice have been recorded after that period of exposure (30–100 days) when the full advantage appears to have been attained, and the limited expectation of life has reached relative stability. For the uninfected standard herd the figure of 58 days has been taken both for new entrants and for survivors at all periods. The two sets of figures for the vaccinated mice in the second mouse typhoid experiment refer to the least and most effective of the four antigenically similar vaccines employed.

TABLE 89

SHOWING LIMITED EXPECTATION OF LIFE (${}_{60}E_x$), IN DAYS, FOR VARIOUS GROUPS OF MICE SUBMITTED TO EPIDEMIC INFECTION.

Ectromelia (*b*)	20·8	52·8	49·1	51·6	—	—

I.P. = Intraperitoneal. P.O. = *Per os.*
N.E. = New Entrants. S. = Survivors after 30–100 days.

The significance of the figures is obvious. With such bacterial infections as mouse typhoid and pasteurellosis residence and survival in an infected herd increases resistance, as measured by expectation of life, but never raises it to the normal level. However long a mouse has lived in such a herd it is never indifferent to the risk that it continues to run. There is no solid immunity.

In the particular case of mouse typhoid, active immunization, by the intraperitoneal injection of two massive doses of a vaccine with an optimal antigenic character, will induce an increase in resistance of the same order as that attained after long residence in the herd. This increased resistance on entry is augmented by life in the infected herd; but vaccination followed by exposure to risk never raises the resistance to the normal level. Here, again, solid immunity is not attained. The effect of *per os* immunization is similar in kind to that of intraperitoneal immunization, though the resistance induced is slightly inferior.

In the case of the virus disease, ectromelia, the natural immunizing response is far more effective. The immunity attained is not complete—old survivors sometimes die of typical ectromelia, even though they have passed through a characteristic attack many months earlier—but it is of a high order. In conformity with this, vaccination with a formolized virus greatly increases the expectation of life of the mice exposed to risk.

It is clearly of interest to determine the effect of immunizing all entrants to an infected herd. Will this procedure result in the elimination of the disease, at least in its overt form? In the particular case of mouse typhoid, it will not.

In an experiment designed to test this point (Greenwood, Topley and Wilson 1931*c*) 3 normal mice were added daily to an infected herd from March 15th, 1929, to May 12th, 1929. The limited expectation of life on entry of these mice was $27{\cdot}00 \pm 1{\cdot}019$ days. From May 13th, 1929, to October 20th, 1929, 3 immunized mice were added daily instead of the 3 normal mice, and from October 21st, 1929, to June 29th, 1930, 1 immunized mouse was added daily to see whether slowing the rate of immigration would have any significant effect on the epidemic prevalence. The ${}_{60}E_x$ figure for the immunized mice added during the three-a-day period was $34{\cdot}92 \pm 0{\cdot}684$ days, for those added during the one-a-day period it was $36{\cdot}38 \pm 0{\cdot}938$ days—results very similar to those recorded above. But mouse typhoid was spreading and killing as actively in June 1930 as it was in March 1929. The mice at risk lived a little longer, but that was all.

It would, of course, be quite wrong to conclude—even if we may justifiably argue from mice to men—that active immunization of such a kind is useless. As has been noted above, it is capable of completely protecting a proportion of mice against a single experimental infection with a dose of living bacilli that is fatal to unvaccinated controls. Under conditions in which exposure to risk is slight, transient or intermittent, a resistance of this order may make all the difference between escape and infection, or between life and death. The lesson, so far as it is applicable, would appear to be that such resistance does not allow its possessor to ignore the risk of infection. We could not, by universal immunization of such a kind, stamp out a disease irrespective of the sanitary environment.

The Rôle of Bacterial Variation in Herd Infection and Immunity.

This problem, which may well be of major significance for the student of infective disease, is at the moment in a rather curious position. Judging from much of the current epidemiological literature one would assume that the primary question —Do changes in bacterial characters play an important part in epidemic happenings?—had been answered clearly and decisively on a basis of incontrovertible evidence. There is free reference to "epidemic" strains of particular bacteria, to loss and gain of virulence and infectivity during an epidemic prevalence, to secular changes in the pathogenic powers of a particular parasite. But nearly all such writing is really only the writer's way of saying that the disease in question was more prevalent, or more fatal, or spread more rapidly at one time than at another. The difficulty, which has seldom been faced, is that a description of epidemic events is, of necessity, a description of a fluctuating equilibrium between parasite and host. For an increase in bacterial virulence we can substitute a decrease in host resistance, or *vice versa*; the effect, *on balance*, is the same. If our descriptions are to be used as evidence in solving this particular problem the rise in virulence, or the fall in resistance, must be proved, not assumed; and the proof is no easy matter.

That changes in host resistance are quite certainly of primary importance will be obvious from our consideration of the natural history of diphtheria or scarlet fever in man, and of the happenings in herds of mice. It may also be conceded that the introduction into a community of a virulent strain of an organism with the production either of the carrier state or of manifest disease, may initiate an epidemic. It is less evident that changes in infectivity or virulence of the bacterial parasite are responsible for the fluctuations and other changes commonly observed during the course of the epidemic.

Of indirect and suggestive evidence there is plenty. We know that bacteria frequently undergo variation in the laboratory; and we know that avirulent or atoxigenic variants may be isolated from man or animals (see for instance Reimann 1927, Wadsworth and Sickles 1927, Okell 1929). We know also that antibodies acting on the surface antigens of the smooth virulent forms of bacteria are in many cases capable of inducing the S $\longrightarrow$ R variation (see for instance Griffith 1923). We know that many epidemic diseases have displayed wide secular fluctuations in their fatality. Taking our biological and epidemiological knowledge as a whole, the conclusion that bacterial variation plays an important part in epidemic happenings seems so probable that an experimental answer in the opposite sense would certainly be suspect—suspect to the extent that we should want to be very sure that our experiments had been properly planned, and that our conclusions had not been arrived at by an unjustifiable inductive generalization from a few particular instances. Experiment, combined with carefully controlled bacteriological and immunological observations in naturally occurring epidemics, must, of course, be our final court of appeal; but neither from this source nor from any other should we accept hasty judgments.

The experimental data at present available may be summarized as follows:

Webster and his colleagues (Webster 1923*a*, *b*, *c*, *d*, 1924*a*, *b*, *c*, *d*, 1925, 1926, 1927, 1928, 1930*a*, *b*, *c*, Webster and Burn 1926, 1927*a*, *b*) have shown quite clearly that different strains of the same bacterium, isolated at different periods of the same epidemic prevalence, may possess an approximately equal virulence as judged by direct inoculation tests, including inoculation into the stomach through an œsophageal tube. This, indeed, was their constant finding with the strains they examined. They conclude that changes in bacterial virulence play no part in the fluctuations in mortality that may be observed at different stages of a long-continued epidemic prevalence. These they would regard as due to changes in the average host resistance, and particularly to innate differences among the hosts at risk, or to seasonal or dietetic factors, that affect resistance in some non-specific way. They have, however, recorded differences in virulence among strains of the same bacterial species isolated from different epidemic prevalences of the same infective disease (Webster 1930*d*, Hughes 1930, Hughes and Pritchett 1930, Pritchett, Beaudette and Hughes 1930*a*, *b*), and they would regard these differences in virulence as determining certain observed differences in behaviour between one epidemic and another —for instance, differences in the proportion of carrier infections to fatal cases of the disease. More recently Webster and Clow (1933) recorded an interesting series of observations on the variations in the virulence of pneumococci for mice. They found that a strain of high virulence, as judged by intraperitoneal injection, might be of low virulence as judged by injection into the nasal cavity; and that a strain of high initial intranasal and intraperitoneal virulence might, as the result of passage from nose to nose, lose all, or almost all, its intranasal virulence, without affecting its intraperitoneal virulence. These findings did not, however, lead them to modify their earlier conclusions.

We have so far considered variations in *virulence*; but virulence may not be

the only factor concerned. If we assume the possible existence of another factor, labelling it *infectivity* and defining it as the *capacity to spread from one host to another under any specified conditions of exposure to risk of infection*, we may inquire whether infectivity is so highly correlated with virulence that we may regard them as synonymous terms.

The evidence available (Topley, Greenwood, Wilson and Newbold 1928) suggests, as would be expected, that those strains of *Salm. typhi-murium* that are capable of spreading rapidly among a herd of mice, giving rise to severe epidemics of mouse typhoid with a high mortality rate, are always of relatively high virulence as judged by direct intraperitoneal inoculation, and that strains of low virulence are incapable of giving rise to severe epidemics, or of spreading widely among the herd at risk, although they may persist for long periods in the tissues of the originally infected hosts, and may give rise to a few latent infections, or even to an occasional death, among the normal mice exposed to risk.

The correlation between virulence and the power to induce severe epidemics by contact infection does not, however, hold with all strains of *Salm. typhi-murium*. A particular strain of this organism, isolated originally from an infected mouse, was found to possess an unusual combination of characters (Topley, Greenwood and Wilson 1931). It was of moderately high virulence, killing in repeated tests some 65–75 per cent. of mice inoculated with 100–1,000 bacilli, but it possessed little power of producing severe epidemics by contact infection. In six closed epidemics, in each of which 100 normal mice were exposed to infection from 25 infected companions, the average limited survival time of the exposed mice ($_{60}E_x$) was 51·27 days—not far short of the normal limit. The proportion of the survivors harbouring *Salm. typhi-murium* in their spleens at the end of the period of observation was, however, high—an average of 31 per cent. for the six epidemics. Data were available for two other groups of epidemics, initiated with two strains of *Salm. typhi-murium* of low virulence as tested by direct inoculation. In one group the average $_{60}E_x$ was 52·62 days, in the other 52·21 days—figures almost identical with those obtained with the more virulent strain—but the percentage of infected survivors was 9·7 in one group and 9·0 in the other, less than one-third of the figure recorded for the relatively virulent strain. This strain had therefore the following combination of characters: a relatively high virulence when injected into the tissues, a considerable power of contact spread with the production of latent infections, but a relatively slight power of producing fatal contact infections.

It was of obvious interest to test the resistance to contact infection, with a highly virulent and infective strain, of survivors from these six epidemics of latent infection, and to compare it with the resistance of survivors from more fatal epidemics and with that of artificially immunized mice. An experiment carried out along these lines gave the results shown in Table 90.

TABLE 90

	Average $_{60}E_x$.	Per cent. Surviving on 60th Day.
Normal mice	37·49 ± 2·613	36·7
Vaccinated mice	41·95 ± 1·529	53·0
Survivors of severe epidemics	48·31 ± 1·836	66·0
Survivors of mild epidemics	48·75 ± 1·861	69·0

Thus the survivors from these mild epidemics were much more resistant than normal mice, significantly more resistant than vaccinated mice, and just as resistant as the survivors from epidemics of greater severity, involving a more stringent mortuary selection. The strain that gave rise to these mild epidemics might, perhaps, be regarded as one in

which the natural immunizing activity was greater than the natural killing power. Clearly, *if* a strain of this character made its appearance during an epidemic prevalence it *might* exert a significant influence on the course of events. But we cannot disregard the *if*.

In more recent experiments on epidemic pasteurellosis (Greenwood *et al.* 1936), results were obtained that seem to afford a satisfactory proof that changes in infectivity do occur during the epidemic spread of a bacterial parasite. Certain strains of *Pasteurella* that originally possessed little power of contact infection, though they were of moderately high virulence as judged by direct inoculation into mice, have, during their slow and limited spread in an experimental herd, given rise to variants in which the capacity for rapid and fatal spread was well developed. These experiments, like that recorded above, do not indicate a complete correlation between virulence and infectivity. If we adopt a term that is very commonly, though a little loosely, employed in current literature, and speak of an *epidemic strain* of a particular bacterial species, defining it as a *strain that has the capacity to spread naturally among a herd at risk giving rise to a severe and fatal epidemic*, we might hazard the guess that an epidemic strain is characterized by two attributes, high virulence and high infectivity, and that it may lose its epidemic character by losing either attribute. On what infectivity, as apart from virulence, depends we have as yet no knowledge. It does not depend primarily on an ability to multiply *in the tissues*: for a strain may be highly virulent but not highly infective. It must presumably depend on adaptations that enable it to meet those environmental changes that are associated with transfer from host to host, and to establish in the recipient host a primary focus of infection from which subsequent tissue invasion can occur. But to say this is merely to define our problem a little more closely.

In summary; variations in virulence in a bacterial parasite during an epidemic prevalence have often been sought for with negative results. There is, however, experimental evidence that different strains of the same bacterial parasite, possessing different degrees of virulence or of infectivity, produce very different results when they are allowed to spread by natural infection among a susceptible herd. There is also evidence that a bacterial parasite may vary in infectivity during an experimental epidemic. Taking the experimental evidence as a whole, it would seem to accord quite well with the view, expressed by many epidemiologists, that variations in the characters of the parasite are of major importance in the spread of human infections, and that an outbreak of disease may be initiated by the evolution, or importation, of an "epidemic strain" of the causative organism. Nevertheless, it seems likely that the evolution within any parasitic species of a strain of high epidemicity or virulence is an occasional event, rather than part of a normal or periodic process determining the fluctuations in mortality and morbidity that may occur during a long-continued epidemic.

The Rôle of other Factors in Herd Infection and Herd Immunity.

All those factors that affect the resistance of the individual will affect the average resistance of the herd of which he is a member. Those factors that have been adequately studied have been considered more or less briefly in earlier chapters.

There are, as we have said, special factors, such as the spatial distribution of the hosts at risk, the duration or the intermittency of contact, and other conditions of arrangement or environment, that affect herds but not individuals. Some of them, particularly those concerning the dispersal and aggregation of the infected and uninfected members of a herd, have been studied experimentally (Greenwood *et al.* 1936, 1939).

In one experiment, susceptible mice were added at a steady rate to an already infected

herd. With low rates of addition, up to 1 or 2 mice each day, the death rate showed wide and irregular fluctuations, with occasional intermissions. With higher rates of addition, the death rates showed minor fluctuations, without intermission, round an almost steady average value; in the circumstances the population increased rapidly at first, and later more slowly, suggesting that a still higher rate of addition would have produced a stable population in which the daily deaths equalled the daily additions. Thus, continuous contact of infected animals with susceptibles introduced into the herd at a steady rate did not produce a system with any inherent tendency to fluctuate, as epidemics fluctuate in natural conditions.

The effect of discontinuous contact was tested in another experiment. Twenty-five mice were infected with *Salm. typhi-murium*. These, and 100 normal mice were kept each in a separate cage. Three times weekly, all the mice were herded in one large cage for 4 hours and at the same time 2 normal mice were added to the herd. An epidemic started among the normal mice, but soon died down, and after 70 days, there were no deaths from mouse typhoid. By the 149th day, the population of mice had increased to 180, and there had been no deaths for 80 days. The population was then aggregated in a single cage. An epidemic wave resulted from this continuous contact, and in spite of the addition of 6 new mice per week, the total population had fallen by the 289th day from 180 to 44 mice. The resumption of discontinuous contact at this time was followed by a prompt response in the reverse direction. The death rate sank and remained at a low level, and the population rose to over 100 mice. These conditions were maintained by intermittent contact over a period of 15 months, at the end of which re-aggregation again produced a major epidemic, which within 30 days reduced the population to 20.

The effect of dispersal upon the course of an experimental epidemic was found to depend on the degree of dispersal and the age of the epidemic. Thus the dispersal of 100 mice into four groups of 25 had little effect upon an epidemic that had just begun to spread. If the mice were divided into smaller groups as, for example, 10 groups of 10 mice, the subsequent mortality was much lower than that of a control group of 100 maintained as a single unit. When dispersal was delayed until the epidemic was well under way, it had little effect, even though the dispersed groups were small (Topley 1922, Topley and Wilson 1925, Greenwood *et al.* 1930). These are results with epidemics in closed herds. The effect of dispersal was also tested in an infected herd in which a continuous spread of infection was maintained by the addition of susceptible mice in large batches at short intervals. Mice were withdrawn to isolation in single cages, after varying intervals of exposure to infection, and the rates of infection and mortality compared with those of added mice left in the herd. The average mortality of mice subsequent to withdrawal was lower than that of their contemporaries left in the herd. The advantage of withdrawal was marked for all periods of exposure up to the longest tested, which was 35 days. The greatest effect, as would be expected, was observed in mice withdrawn after the shortest exposure (Greenwood *et al.* 1939).

The conclusions to be drawn from these experiments, though they must in some cases be tentative, add to the evidence that has accumulated from the study of natural epidemics in man and animals, and point to the fact that movements of susceptible and infected hosts in relation to one another, and the aggregation or dispersal of human or animal herds, apart from any introduction of new infection, are sufficient to induce major changes in the incidence of many infective diseases (Topley 1942; see also McKendrick 1940). Many other factors have been studied in far greater detail but with less control under field conditions. Some day we may be able to work these factors into our immunological picture in terms of the effects produced by changes in the rate at which infection is received, or in the rate at which immunization proceeds (see for instance Dudley 1923); but that day has not come yet.

The Control of Herd Infection. The study of herd infection and herd immunity by the methods described above is as yet in its infancy but it has already modified many of our conceptions with regard to the administrative control of epidemic disease. Isolation and quarantine, for instance, have, in the past, played a major part in public health administration. A very cursory consideration of the various types of distribution of a bacterial parasite within an infected herd that have been described earlier in this chapter, and of the results obtained in experimental epidemics, will raise serious doubts as to the probable efficacy of such measures. In the case of quarantine, it is clear that it can succeed only where it is complete ; and the history of sanitary control suggests that successful quarantine is possible only under very exceptional conditions, and over relatively short periods of time. The carrier and the atypical case defeat a sanitary barrier, just as they defeat isolation ; and, under the conditions of modern transit, there seems little possibility of preventing the introduction into any one part of the inhabited world of any infective parasite which is prevalent in another. Once the barrier is passed, the subsequent course of events will depend upon the conditions obtaining within the community into which infection has been introduced.

The policy of the isolation of sick persons within a community is based on a similar failure to realize that the clinical picture provides a very incomplete description of the true state of affairs. If isolation removed from the community the whole, or even the great majority, of the infected individuals, it might be expected to exert a considerable influence on the prevalence of an infective disease. But if the ratio of latent or atypical infections to clinically recognizable cases is high, we cannot hope to effect any marked reduction in the morbidity rate by removing to hospital those cases which exhibit the typical stigmata of the disease. We may indeed effect a smaller reduction in the total infective material than the ratio of isolated to non-isolated, among infected individuals, would suggest ; for the sick person would, in any case, move less freely among his fellows than the apparently healthy carrier. As in the case of quarantine, we should expect a policy of isolation to be successful only in exceptional circumstances, when the recognizable cases form a very high proportion of the total infected, and when the total mass of infection to be dealt with is small. Once a given infective disease has assumed an endemic-epidemic prevalence within a herd, we should expect no appreciable result from the isolation hospital, so far as a reduction in morbidity is concerned. It is interesting to find that the expectations based on bacteriological and experimental findings are borne out by administrative experience. Thus, an attempt has been made, by an analysis of the available records, to answer the question : Does hospital isolation have any effect upon the incidence of scarlet fever ? All applications of the calculus of correlations have wholly failed to bring out any connection whatever between the incidence rate of scarlet fever and the extent of isolation (see Greenwood and Topley 1925). The value of the isolation hospital must apparently be judged by the benefit which it confers on the sick within its walls ; for it would seem to have little effect on the health of the community as a whole.

Turning to those administrative measures which bring about a general reduction in the opportunities for the transference of infection from host to host, theoretical considerations suggest that action along these lines is likely to be effective. Any improvement in sanitation, which ensures a clean water, or milk, or food supply, which reduces the frequency of insect vectors of infection, or which lessens the opportunities for close contact between individuals, may be expected to lead to

a reduction in the incidence of those infections, with the transference of which that particular measure of sanitation interferes. This expectation has been fulfilled whenever an effective method of reducing the general opportunities for the transference of a particular infection has been adopted.

It may be noted that it is in the case of infections of the respiratory tract that it is particularly difficult, under modern conditions of civilization, to devise any generally applicable and effective means of preventing transit of the parasite from host to host, and that it is exactly these diseases which have so far largely defied the attacks of preventive medicine (see Chapter 91).

Finally, the whole trend of our present knowledge stresses the importance of the susceptible host. Any measure which increases the average resistance of a herd, whether it depends on specific immunization, or on some factor which confers an increased immunity less specific in its range, will exert a direct influence on the incidence of the corresponding infections. The accurate determination of the conditions which must be fulfilled, in order that induced variations in immunity should exert their optimal effect, and the development of methods by which such immunity can be induced, are two of the most important problems which await solution.

PART IV

THE APPLICATION OF BACTERIOLOGY TO MEDICINE AND HYGIENE

CHAPTER 57

ACTINOMYCOSIS, ACTINOBACILLOSIS, AND RELATED DISEASES

Introductory

The term Actinomycosis was originally given by Bollinger in 1877 to a disease in cattle characterized by the formation of a hard wooden swelling of the tongue or a fusiform enlargement of the jaw. In the lesions of this disease he found numerous opaque slightly yellowish bodies of coarsely granular or mulberry-like appearance, which were found to consist of a fungus. His colleague Harz, a botanist, to whom he referred for an opinion on this organism, decided that it was a true mould and suggested for it the name of ray fungus or *Actinomyces bovis*. A similar mycotic disease in man was described the following year by Israel (1878, 1879); and in 1879 Ponfick suggested that the two diseases were identical. From seven cases of actinomycosis in cattle, Bostroem in 1891 isolated an aerobic filamentous organism showing true branching; and from two cases in human beings, Wolff and Israël in the same year (1891) isolated a similar branching organism, which was, however, anaerobic. In 1902 Lignières and Spitz described a new disease in cattle, differentiated from actinomycosis chiefly by its tendency to invade the lymph glands. From the affected animals they cultivated a very small, non-branching, Gram-negative bacillus, to which they gave the name actinobacillus. The disease they called actinobacillosis.

As early as 1874 Vandyke Carter drew attention to a disease in India known as Madura foot. Microscopical examination revealed the presence of a fungus, but attempts to cultivate it were unsuccessful till 1894 when Vincent succeeded in isolating an aerobic branching filamentous organism, similar in many respects to *Actinomyces bovis*, which he called *Streptothrix maduræ*.

From the disease known as "Farcy of cattle," Nocard in 1888 cultivated an aerobic branching filamentous organism, which likewise resembled Bostroem's *Actinomyces*. Similar branching organisms have been encountered in a number of diverse lesions in human beings and other animals.

From this brief description, it will be realized that there are several diseases from which actinomyces-like organisms have been isolated. In one group of diseases, their proliferation occurs in the form of colonies which have a definite ray structure; such colonies are seen in the pus as granules or *Drusen*. In

another group the organisms form a felted mycelium without any radial arrangement, and without any formation of granules. Some authors prefer to limit the term actinomycosis to diseases of the former group, denoting those of the latter group by such terms as Streptothricosis, Cladothricosis, Oosporosis, Pseudotuberculosis, Para-actinomycosis, or Pseudo-actinomycosis. In Chapter 14 we have given our reasons for including all the filamentous branching organisms in the *Actinomyces* group. The logical sequence of this is to classify all diseases caused by these organisms under the name of Actinomycosis. This term, however, is often used in a broad sense to include chronic granulomata characterized by club formation. Such granulomata are in fact sometimes caused by *Staph. aureus* or *C. pyogenes*, and though their inclusion may be justified on clinical grounds, it leads to great confusion bacteriologically. We therefore propose to exclude from Actinomycosis the granulomatous lesions of cattle and swine that are caused by organisms other than those belonging to the *Actinomyces* group. The staphylococcal lesions are better referred to as Botriomycosis (see Chapter 67).

ACTINOMYCOSIS.

A. Due to *Actinomyces bovis* of Wolff and Israël. True ray-fungus disease in man and cattle. Granules or *Drusen* formed in tissues. Anaerobic.

B. Due to *Actinomyces*—aerobic types.
   (1) Non-acid-fast group. Madura foot—granules found in tissues. Other lesions in man and animals—no granules found in tissues.
   (2) Acid-fast group—chiefly pulmonary and abdominal infections in man. No granules formed in tissues. Farcy of cattle—no granules formed in tissues.

C. Due to *Actinomyces muris*. Rat-bite fever (one type) in man, and infective arthritis in mice. No granules formed in tissues.

ACTINOBACILLOSIS.

Due to bacilli.
   (1) *Actinobacillus lignieresi* of Lignières and Spitz. Actinobacillosis in cattle. Granules or *Drusen* formed in tissues.
   (2) *Actinobacillus actinoides* of Theobald Smith. Broncho-pneumonia of calves: pneumonia of rats. No granules formed in tissues.

ACTINOMYCOSIS

A. Due to Actinomyces bovis Wolff and Israël

Epidemiology.—Actinomycosis in man is not a common disease. According to van der Hoeden's (1939) observations in the Netherlands, it is three times as common in males as in females, and ten times as common in rural districts as in large towns; about 80 per cent. of the cases occur in patients over 20 years of age. The cervico-facial region is the commonest situation attacked. Table 91, which we have compiled from cases observed by Illich and by Leith (see Delépine 1915), and Colebrook (1921), indicates the distribution of the lesions. Cope (1938) has collected a rather larger series of cases in his monograph on actinomycosis, but the percentage distribution is much the same.

The mortality of the disease depends largely on the site affected. Of 10 cases of cervico-facial infection observed by Colebrook (1921), 9 recovered: on the

other hand 12 out of 14 thoracic and abdominal infections proved fatal. Of 87 cases recorded by Harbitz and Gröndahl (1911), 42 died or remained unhealed.

TABLE 91

DISTRIBUTION OF ACTINOMYCOTIC LESIONS IN MAN.

	Cases.	Percentage.
Head and neck	234	51·4
Tongue	16	3·5
Abdomen	99	21·8
Thorax	65	14·3
Skin	11	2·4
Other situations and doubtful	30	6·6
	455	100·0

The extent to which *cattle* are infected is difficult to ascertain, largely because the disease has so frequently been confused with actinobacillosis. According to Jelenevski (see Hutyra and Marek 1926) the morbidity, as estimated in various abattoirs from 1896 to 1911, was as follows: Berlin 0·31 per cent., Vienna 0·01 per cent., Moscow 3·34 per cent., Kief 0·67 per cent., and Warsaw 0·65 per cent.; but the mild form of lingual actinomycosis was apparently not included in these statistics. Even in the same country, the frequency appears to vary from one part to another. Thus, in the Netherlands, van der Hoeden (1939) gives the incidence of lesions in slaughtered cattle as ranging from 0·42 per 1,000 in Gouda to 12·17 in Amsterdam. Of 85,445 tongues imported from the Argentine and examined by MacFadden (1913) in London from August to October 1913, 4,949 or 5·8 per cent. showed lesions, but there is evidence to suggest that many of these were infected with the actinobacillus. In this country the disease is not infrequent. It is stated to be commoner in low-lying marshy districts, and to affect stall-fed cattle more frequently than those fed on pasture. According to Magnusson (1928), it affects almost exclusively the jaw bone, which develops a typical fusiform swelling; but Albiston and Pullar (1934) state that the soft tissues—tongue, lymph and salivary glands, muscle—may be affected. Of 1,015 cases observed in abattoirs in the Netherlands, 900 affected the head, 61 the lungs, 11 the abdominal organs, 32 lymph glands, 10 the udder, and 1 the foot (van der Hoeden 1939). Generalization of the infection is not uncommon in man, but is rarely seen in cattle. So-called actinomycosis of the udder in cattle seems to be almost invariably due to staphylococcal infection (Magnusson 1928, Albiston 1930).

Actinomycosis is by no means infrequent in *swine*. The udder is attacked. Magnusson (1928) states that two types of *Actinomyces*, both anaerobic, may be found, which differ from the *bovis* variety. Some cases are due to staphylococci, and are more correctly termed botriomycosis. The disease occurs rarely in sheep, goats, and dogs. Most carnivora are resistant. We have met with one case in a mouse, in which the liver showed typical actinomycotic lesions.

Mode of Infection.—The mode of infection both in man and animals is obscure. In the days when Bostroem's organism was held to be the cause of the disease, it was generally thought that infection was conveyed by grasses, which lodged in the mucosa and provided a suitable nidus for the development of the organism. This

view appeared probable because the organism was found to lead a saprophytic existence outside the body, being frequently isolated from grasses and cereals, and because awns of grasses, or barley spikes, are not uncommonly found in the actual lesions. But now that Bostroem's organism is regarded as an accidental contaminant, and the organism isolated by Wolff and Israël as the true cause of the disease, this hypothesis has been abandoned. Wolff and Israël's organism appears to be a strict parasite; it has never been found outside the animal body, and its survival in artificial culture is brief. These facts suggest that the disease is transmitted by infected pus, saliva, or nasal discharge.

Strong evidence in favour of this view is provided by the work of Naeslund (1925, 1926, 1929) who, in a study of the flora of the human mouth, succeeded in isolating both aerobic and anaerobic types of *Actinomyces*. The anaerobic types were indistinguishable from *Actinomyces bovis*, and were more frequently met with than the aerobic types. They were, moreover, isolated from a high proportion of salivary calculi, thus supporting Söderlund's (1921) view that the formation of these calculi must be regarded as a specific result of actinomycotic infection. The same organisms also seemed to play an important part in the development of dental tartar. Bibby and Knighton (1941) regard Naeslund's micro-aerophilic and anaerobic strains as probably belonging to the *Leptothrix* group; but the work of Lord and Trevett (1936), Emmons (1938), Sullivan and Goldsworthy (1940), and Slack (1942) seems to leave little doubt of the occurrence of true *Actinomyces* strains, indistinguishable from the Wolff-Israël type, in the human mouth, notably in diseased tonsils, carious teeth, and pyorrhœal pus. If this organism is accepted as an inhabitant of the human mouth, the factors predisposing to the development of actinomycosis have still to be determined. Possibly suitable necrotic foci, such as septic teeth, have to be present in which the organisms can develop under anaerobic conditions. There are records of three cases in which the disease followed a human bite (see Robinson 1944).

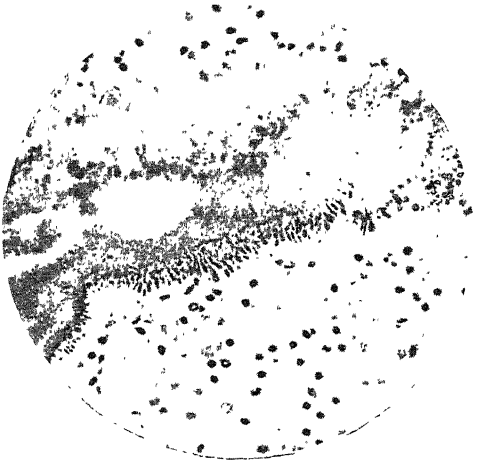

FIG. 269.

Part of the edge of a colony of *Actinomyces bovis* in the jaw of an ox, showing the peripheral zone of clubs (× 350).

Bacteriology.—In the tissues *Actinomyces* grows in the form of colonies or *Drusen*, which macroscopically have the appearance of small granules. A section suitably stained reveals the presence of a central mass of partly necrotic material, in which branching filaments may be recognized, and a peripheral zone of swollen bodies looking like clubs and arranged radially. The clubs are surrounded by pus cells, outside of which there are aggregations of mononuclear cells and dense masses of fibrous tissue. The colony often presents a characteristically scalloped edge. The mode of formation of

the clubs is still under dispute, some workers maintaining that they represent the swollen extremities of the filaments, others that they are due to a reaction on the part of the tissues. The fact that they occur in so-called actinomycotic lesions due to staphylococci, and that they may be formed under experimental conditions around dead masses of tubercle bacilli and actinomyces, suggests that the second explanation is more probably correct. The disease spreads by contiguity; the surrounding tissues, no matter of what type, are invaded and destroyed.

The pus discharged from these lesions is not usually abundant; it is yellow, often bloody, thick or thin, and sometimes tough and viscous. If shaken up with water in a test tube it will be seen to contain small granules, which rapidly sink to the bottom. They vary greatly in size, but are generally about 0·25 to 1 mm. in diameter; they are opaque, spherical bodies, greyish-white by reflected and yellowish by transmitted light, and have an oily appearance. Generally they are soft and can be readily crushed, but in cattle they may be hard or even calcified. In pus from old lesions they are darker in colour, and not infrequently brown. Microscopical examination of these granules reveals the presence of a felted mycelium, together with rod-shaped and coccoid bodies, surrounded by radially disposed clubs. The filaments are irregularly Gram-positive; the clubs are usually Gram-negative. Clubs are said to be more conspicuous in lesions of cattle than in those of man.

Though all observers are agreed on the microscopical appearance of the organism in the tissues, attempts to cultivate it have led to divergent results. Bostroem in 1891 was the first to report positive results. By inoculating several hundred tubes of medium from a few cases of actinomycosis in cattle he succeeded in obtaining about 12 cultures of an aerobic, branching, pigmented, filamentous organism. Although he was unable to reproduce the disease in animals by injection with this organism, he had no hesitation in concluding that it was the cause of the disease. A little later in the same year Wolff and Israël (1891) reported the isolation of an anaerobic, branching, filamentous organism from 2 cases of human actinomycosis. (For a description of these organisms see Chapter 14.) Attempts to reproduce the disease experimentally in laboratory animals with this organism were not very successful; at the most, small, apparently retrogressive, granulomatous tumours resulted from inoculation. In 1905 Wright in Boston carried out a more thorough investigation. From 13 cases of actinomycosis in man and from 2 in cattle he isolated in pure culture an organism of the Wolff-Israël type, but like his predecessors was unable to produce progressive disease by animal inoculation. From a critical résumé of the literature, however, he reached the conclusion that the Wolff-Israël organism was the true cause of actinomycosis. Bostroem's organism he regarded as an example of the numerous saprophytic fungi which are common on grains and grasses, and which are therefore liable to gain access as contaminants to actinomycotic lesions.

Subsequent work tended more and more to confirm Wright's conclusions. The observations of Henry (1910), Colebrook (1920) and Bosworth (1923) in this country, of Harbitz and Gröndahl (1911) in Norway, and of Magnusson (1928) in Sweden left little doubt that the Wolff-Israël type was the principal organism responsible for actinomycosis in man and cattle. Colebrook showed that the serum of severely infected human patients might agglutinate this organism; and Magnusson found that, though the disease could not be satisfactorily reproduced

in small animals, it was possible to set up typical actinomycotic lesions by the inoculation of pure cultures into cattle. That it has not been cultured from all cases of the disease is probably explained by technical difficulties, especially when the lesion is invaded by secondary organisms, and by the not infrequent sterility of granules from old lesions.

We may conclude that the evidence in favour of the ætiological rôle of the *Actinomyces bovis* described by Wolff and Israël is sufficient to justify us in accepting this organism as the cause of that variety of actinomycosis which is characterized by the presence in the tissues of the typical ray fungus.

One further point in connection with the bacteriology of the disease may be mentioned. In the characteristic granules it is not unusual to encounter, as well as the branching filaments of *Actinomyces*, densely packed masses of Gram-negative cocco-bacilli. These organisms were first described and isolated by Klinger in 1912 who named them *B. actinomycetem comitans*; and they have been subsequently noted by Colebrook (1920) in this country, and Bayne-Jones (1925) in America. What relation these organisms bear to *Actinomyces bovis* is not clear. (For further information see Chapter 14.)

Diagnosis, Prophylaxis and Treatment.—Diagnosis is made by microscopical and cultural examination of the affected tissues. The granules should be crushed between slides and stained by Gram's method. If calcified, they should first be treated with hydrochloric acid. The presence of a mycelium of Gram-positive filaments surrounded by radially disposed Gram-negative clubs is characteristic of actinomycosis. Cultures are made from fresh young granules only; after thorough washing, they are seeded into a number of tubes containing blood broth (Gordon 1920), glucose agar, or serum agar; incubation is carried out under both aerobic and anaerobic conditions, preferably in an atmosphere to which 5–10 per cent. CO_2 has been added. Rosebury, Epps and Clark (1944) prefer to streak the unwashed granule or the pus on to four plates in series of Bacto brain heart infusion agar and to incubate in an anaerobic atmosphere to which 5 per cent. CO_2 is added. Primary cultures are frequently contaminated; single colonies should therefore be picked off to obtain pure cultures. Examination of the agglutinating power of the patient's serum to the organism isolated should be carried out if possible. In pulmonary actinomycosis in man the sputum is tough, often viscous, and sometimes hæmorrhagic; the typical granules can be found on examination (Harbitz and Gröndahl 1911). Most of the abdominal cases commence in the appendix. In the rare cases of actinomycotic meningitis, the primary lesions are generally in the lungs and bronchial glands (Henry 1910).

As we are still ignorant of the factors determining the development of the disease, it is difficult to lay down prophylactic measures against it. It is clear, however, that the discharge from the lesions should be considered dangerous, and every care taken to prevent its coming into contact with man or other animals.

Colebrook (1921) reports favourably on vaccine therapy, provided efficient surgical drainage of the affected tissues is secured. Negroni (1937) claims to have obtained promising results with a formolized filtrate of broth cultures of parasitic aerobic strains of *Actinomyces*, employed presumably to stimulate a non-specific protein reaction. Penicillin treatment now seems to hold out greater promise of success.

B. Infections due to, or associated with, the Aerobic Members of the Actinomyces Group

(1) Madura Disease.

This disease, which is peculiar to man, was first thoroughly investigated by Vandyke Carter of Bombay in 1874. It occurs chiefly in India, but cases have been reported in Algiers, Italy, Roumania, America, and other countries. The lesions are commonest in the foot, and are of a chronic granulomatous nature, characterized by swelling, suppuration, and sinus formation. The pus contains granules, which in some cases are yellowish in colour, in others black. These granules are generally larger than those seen in actinomycosis—up to 1 mm. in diameter; they may be aggregated into masses looking not unlike fish-roe (Kanthack 1893). Under the microscope, those from the pale or ochroid variety of the disease consist of a central irregularly staining felted mycelium, showing true branching; sometimes they are surrounded by a ray formation of club-like structures. Vincent (1894) cultivated from them an aerobic filamentous organism, which gave a pink or rose coloration on potato (see Chapter 14). It proved to be practically non-pathogenic for laboratory animals. He called it *Streptothrix maduræ*; its correct name is *Actinomyces maduræ*.

Wright (1898) found that the granules from the black or melanoid type of the disease consisted of a mycelium of hyphæ or fungoid elements, more or less degenerated, embedded in a hyaline brown-coloured refringent substance, which itself formed more or less of a reticulum. The pigment could be dissolved by sodium hypochlorite solution, leaving the mycelium unaltered. Cultures resulted in the development of a mould, consisting of a branching septate mycelium, and forming typical mould-like colonies. Wright concludes that the pale variety of the disease is due to an organism of the *Streptothrix* (*Actinomyces*) group, while the black variety is due to a mould or hyphomycete. This view is supported by the observations of Tribedi and Mukherjee (1939). It is probable that several types of organism are responsible for the disease, and that the pale variety, at least, may be caused either by an *Actinomyces* or by a fungus.

(2) Other Lesions in Man.

Eppinger (1891) described a case of brain abscess in a glass-grinder due to a branching filamentous organism. Old calcified abscesses were found in the bronchial and supraclavicular glands, and pseudotubercles were noticed in the lungs and pleura. The organism grew abundantly on ordinary media under aerobic conditions (see Chapter 14). Injection into rabbits and guinea-pigs proved fatal in 1 to 4 weeks; post mortem the lungs, liver, and spleen were studded with small white nodules. He called the organism *Cladothrix asteroides* (*Actinomyces asteroides*) and the disease Pseudotuberculosis cladothrichica. Later MacCallum (1902) recorded a case of peritonitis in a negro child due to infection with the same organism. According to Claypole (1913) this organism is mildly acid-fast.

Henrici and Gardner (1921) isolated a similar organism from the sputum of a woman, which differed, however, in certain particulars, and which they called *Actinomyces gypsoides*. From the literature they were able to gather accounts of 26 cases of infection with acid-fast *Actinomyces*. Infection probably occurs by inhalation; the first lesions are in the peribronchial nodes. Later, caseous broncho-pneumonia develops, followed by central softening and cavity formation. Metastases may occur. The duration of the illness is generally about 6 months.

These cases are liable to be confused with tuberculosis. Goldsworthy (1937) recommends that the organisms should be sought for in the sputum of all patients with obscure or unusual chronic infections of the lungs, especially when repeated attempts to demonstrate the tubercle bacillus have failed. The organisms are liable to be decolorized in the ordinary Ziehl-Neelsen process, but their filamentous morphology is rendered strikingly evident by Gram's strain. Cultivation of the organism, and the exclusion of tuberculosis by inoculation of the sputum into guinea-pigs, should effect a differential diagnosis.

Actinomyces of the aerobic non-acid-fast type have been described in various lesions by numerous authors, such as in the bladder and prostate of a man with pyuria by Cohn (1913), in the purulent cornea by Namyslowski (1912), in the cerebro-spinal fluid of children with meningitis by Gerbasi (1927), and in a fatal infection of the lungs by Biggart (1934).

(3) **Cattle Farcy. Farcin du bœuf.**

Cattle farcy is characterized by the appearance—generally on the medial surface of the extremities—of firm, painless perivascular nodes, which later suppurate. When incised, they discharge a whitish, odourless mass resembling soft cheese (Report 1913). The regional lymph glands become converted into firm, painful tumours. It is a chronic disease lasting for a year or more, and marked in the later stages by severe cachexia. From the pus of an affected animal Nocard (1888) isolated an aerobic branching organism, now known as *Actinomyces farcinicus*. Intravenous injection of pure cultures into a cow and a sheep resulted in the development of miliary nodules. The disease is not common in Europe; it is very prevalent in Guadeloupe, and has been recorded in India, and in Kenya (Daubney 1927).

(4) **Other Lesions in Cattle.**

Evans (1918) has recorded an infection of the udder of cows with an organism of the aerobic *Actinomyces* group. She succeeded in isolating it from 18 out of 21 samples of milk, in which it was present in considerable numbers.

(5) **Goats and Horses.**

Silberschmidt (1899) isolated a member of this group from three goats; this organism is called *Actinomyces capræ*. The same organism was later cultivated by Galli-Valerio from the lung of a goat. Dean (1900) cultivated a member of the group from an abscess in the submaxillary region of a horse.

C. Infections due to, or associated with, the Facultative Aerobic Members of the Actinomyces Group.

(1) **Rat-bite Fever.**

For many years there has been great confusion over the ætiology of this disease. Schottmüller (1914), Blake (1916), Tileston (1916), and others described the isolation of a streptothrix—*Streptothrix muris ratti*—from the blood of patients suffering from rat-bite fever, while Japanese workers (see Chapter 82) brought strong evidence to show that the disease was due to a spirochætal organism known as *Spirochæta morsus muris* or *Spirillum minus*. There seems to be no question now that both organisms may be responsible, and that rat-bite fever may be of at least two different types. The evidence for this conclusion is based on a careful study of the literature.

In 1925 Levaditi, Nicolau, and Poincloux in France described an organism, to which they gave the name *Streptobacillus moniliformis*. It was isolated from the blood of a laboratory worker who was suffering from an acute disease characterized by fever, sore throat, papular erythema, and multiple arthritis. The following year Parker and Hudson (1926) gave an account of an epidemic disease occurring in Haverhill, Massachusetts. This disease they referred to as Erythema arthriticum epidemicum or Haverhill fever. An organism was isolated—*Haverhillia multiformis*—which was subsequently proved to be identical with *Streptobacillus moniliformis*. In neither instance was there any suspicion of infection having occurred through rats. In 1933 Strangeways accidentally encountered the same organism in mice that had died after intraperitoneal inoculation with the blood of rats infected with *Trypanosoma equiperdum*. Investigation showed her that *Streptobacillus moniliformis* was an inhabitant of the nasopharynx of the rat, in which it normally led an apparently harmless existence. A very similar organism had already been reported by Tunnicliff (1916) in the lungs of white rats affected with bronchopneumonia. It would therefore appear that *Streptobacillus moniliformis* is no other than the *Streptothrix muris ratti* of the earlier workers. Both organisms appear to be closely related to the *Actinomyces* group, and we have therefore suggested for them the name *Actinomyces muris*. Since this organism is pathogenic for man and is a normal parasite of the rat, it is not difficult to understand how it may be responsible for human infection. *Spirillum minus* is also a normal parasite of the rat, and may likewise cause rat-bite fever. We shall restrict ourselves at the moment to the description of the type of disease caused by *Actinomyces muris*. For the type caused by *Spirillum minus* see p. 1838

Rat-bite fever due to *Actinomyces muris* is an irregularly relapsing, febrile, septicæmic disease characterized by metastatic arthritis and morbilliform and petechial cutaneous eruptions. The incubation period is usually under 10 days, and may be as short as 3 days. The disease is often ushered in by a chill and a rapid rise of temperature. The wound usually heals without exacerbation. There is extreme prostration, severe generalized muscular pain and tenderness, headache, weakness, and a widespread morbilliform or petechial eruption. Generalized enlargement of the lymph glands may occur. Non-suppurative arthritis, affecting one joint after another, is a characteristic feature of the disease. There is a leucocytosis with a high proportion of neutrophiles. After a few days the temperature falls by crisis, and the disease then assumes a relapsing type, febrile paroxysms occurring at irregular intervals for weeks or months. The case mortality is not known with certainty, but a figure of 10 per cent. may be quoted. Little is known of the post-mortem appearances, but Blake's case showed an ulcerative endocarditis and a subacute myocarditis. Diagnosis during life is best made by cultivation of the causative organism from the blood stream during a febrile attack. About 20 ml. of blood are distributed partly into serum broth and partly over a number of plates of Loeffler's serum. The cultures may be incubated aerobically or anaerobically, preferably in the presence of 5 per cent. CO_2. According to Brown and Nunemaker (1942) agglutinins may be demonstrable in the patient's blood serum in a titre varying between 1/160 and 1/5,120. A suitable antigen may be prepared by formolizing a broth culture of an old laboratory strain of *Act. muris* that forms a homogeneous sediment. Arsenic is worth trying in treatment, but its real value is unknown. According to Heilman's (1940) experimental observations on mice, it is without effect, whereas gold sodium thiomalate protects

the animals against rapidly fatal doses of *Streptobacillus moniliformis*. Though infection usually follows a rat-bite, the outbreak of Haverhill fever studied by Parker and Hudson (1926) was traced to the consumption of raw milk, as was also another outbreak affecting 86 persons described by Place and Sutton (1934). How the milk becomes contaminated it is difficult to say, but the excretion of the organism in the urine of infected mice and perhaps rats affords a possible explanation. The differential diagnosis of rat-bite fever due to *Actinomyces muris* from that due to *Spirillum minus* has been studied by Allbritten, Sheely, and Jeffers (1940). The actinomycetal type has an incubation period usually under 10 days, the wound does not generally become inflamed when the temperature rises, the febrile paroxysms are less regularly periodic, the rash is of the small macular or petechial type, arthritis is a prominent feature of the disease, leucocytosis is common, and the effect of arsenic in treatment is doubtful. In the spirillar type, on the other hand, the incubation period is usually longer than 10 days, the local wound becomes inflamed when the temperature rises and may suppurate, the febrile paroxysms are more regular, the rash is of the large macular or papular type, arthritis is rare, leucocytosis is less common, and arsenic is specific in treatment. Both diseases apparently respond to penicillin treatment (Heilman and Herrell 1944). Reference, however, to the excellent review by Brown and Nunemaker (1942) suggests that, though some symptoms are commoner in one form of the disease than the other, both organisms may give rise to the same clinical picture.

(2) **Infective Arthritis of Mice.**

The natural disease produced in laboratory mice by *Actinomyces muris* has been described by Levaditi, Selbie, and Schoen (1932) and Mackie, van Rooyen, and Gilroy (1933), and in wild mice by Williams (1941). It may occur in either sporadic or epidemic form, and may be of an acute septicæmic or a more chronic polyarticular type. The mortality is high. Infection probably results either through bites, or through contamination with urine, which may contain the organism. In acute cases the animal appears ill and has a lustreless coat. The eyes may be glued together by a semipurulent conjunctival discharge. Death occurs in a few days, and nothing characteristic is found at necropsy. The subacute or chronic type is characterized by polyarthritis and myocarditis, the former evidenced by swelling of the joints, the latter by cyanosis of the tail and extremities. One of the commonest manifestations is œdematous swelling of the feet and legs, sometimes confined to one or both hind limbs. Ulceration of the feet may occur, but gangrene is rarely observed. Paralysis of the hind limbs, enlargement of lymphatic glands, subcutaneous swellings, and keratitis are other manifestations that are not infrequently encountered. The conjunctivitis may suggest infection with *Ery. murisepticа*, the swelling and ulceration of the feet ectromelia. Diagnosis is made by culture. The organism can often be isolated from the blood, even in chronic cases, and from the spleen, liver, glands and joints. Serum agar or Lœffler's serum should be used. Experimental reproduction of the disease in normal mice is readily accomplished by inoculation of pure cultures (see p. 386).

ACTINOBACILLOSIS

In 1902 Lignières and Spitz described under the term actinobacillosis a disease that had occurred in epizootic form amongst cattle in the Argentine during the summer of 1900–01. Once a herd had become infected the disease spread rapidly, attacking 15–25 per cent., sometimes even 50 per cent., of the animals in the course of a few weeks. After a short time the epizootic died down, but sporadic cases, generally of a mild form, occurred at intervals. The main animals attacked were cattle; sheep were rarely, and horses never attacked. In cattle all ages were affected, from calves of 1 month to animals several years old.

In about 80 per cent. of the cases the lesion was in the subcutaneous tissue of the neck; in about 5 per cent. in the tongue. With the exception of the lungs, the internal organs were not often affected. The most striking difference from actinomycosis lay in the frequency with which the regional lymphatic glands were invaded. In the neck the lesion commences as a rounded subcutaneous nodule of fibrous consistence, adherent to the skin, with a smooth but later protuberant nodular surface. During the next few days the lesion grows rapidly, softens in the centre, and becomes converted into a cold abscess. In this state it persists for weeks or months, gradually enlarging. Eventually it ulcerates and discharges a highly viscous, milky-white or slightly green, almost odourless pus, containing little greyish-white opaque granules up to 0·4 mm. in diameter. The pus is so viscous that it is rarely discharged completely; it forms crusts on the surface of a fungating ulcer, which persists indefinitely. The abscesses are usually multiple, and frequently occur in different situations simultaneously—such as the tongue, glands, and lungs. Fibrous tissue is formed around the lesions—as in actinomycosis. On examination the granules are seen to be simple or composite. They consist of tufts of radiating clubs varying in size from about $16 \times 8\ \mu$ to $99 \times 24\ \mu$. They are stained best by glycerol picrocarmine; in a few seconds the clubs take on a yellow colour, while the pus appears pink. No mycelium is found. If, however, the granule is stained with carbol-fuchsin, it is sometimes possible to distinguish small bacilli in the granular detritus that occupies the centre. Both clubs and bacilli are Gram-negative. A very pretty picture is obtained by staining with Ziehl-Neelsen and decolorizing cautiously with 1 per cent. H_2SO_4. The interior of the colony is blue, while the clubs, being weakly acid-fast, are stained red.

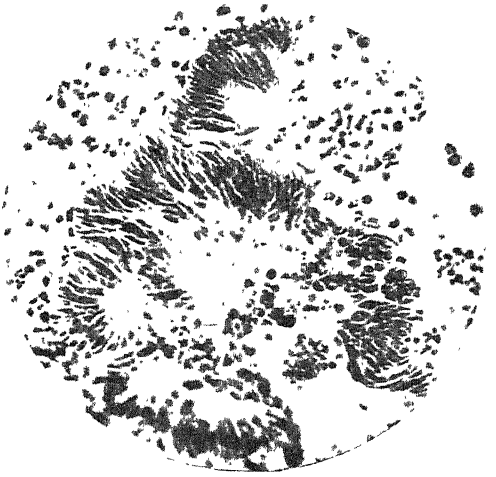

FIG. 270.

A colony of *Actinobacillus lignieresi* in the tongue of an ox, showing the long, finger-shaped clubs (× 350).

Cultures made from the granules revealed the presence of a very small

Gram-negative, non-motile, cocco-bacillus, which Lignières and Spitz called the actinobacillus—now called *Actinobacillus lignieresi.* (For description see Chapter 14.) In this country the disease is less acute, and the lesions are more localized, though the glands are almost invariably affected.

Reproduction of the Disease in Animals.—Subcutaneous inoculation of a pure culture into cattle leads to the formation of an abscess similar to that occurring in the natural disease, though not all strains are virulent. Fluctuation is apparent about the 10th day. The abscess enlarges, and eventually the skin gives way, allowing a small quantity of pus to exude. Fungating masses spring up around the opening and obstruct drainage. The animals gradually waste. The pus contains typical granules. Feeding has not been successful in transmitting the disease. A local abscess develops after subcutaneous inoculation of pure cultures into pigs and sheep. In horses a large œdematous swelling is formed, which discharges pus after a few days.

The work of Lignières and Spitz has been confirmed by workers in several countries. Nocard (1902) recognized the disease in France. He pointed out that in actinomycosis of cattle the granules in the pus are yellowish in colour and often calcified, whereas in actinobacillosis they are greyish-white and rarely calcified. Griffith (1916) examined the diseased tongues and lymphatic glands of 44 cattle slaughtered in this country. Of these no fewer than 40 showed lesions of actinobacillosis. From 23 of these he isolated a Gram-negative bacillus which had the characters of *Actinobacillus lignieresi.* One of the cultures inoculated subcutaneously into a calf caused a local lesion containing typical granules. The remaining 4 cases, affecting the lower jaw, were due to the *Actinomyces bovis.* In an examination of 34 specimens of " actinomycosis " in cattle slaughtered at Islington, Bosworth (1923) recognized *Actinobacillus lignieresi* 21 times; from 17 of the cases he isolated it in pure culture. The other 13 specimens were examples of actinomycosis.

Diagnosis.—The important points are: (1) The location: practically all jaw lesions appear to be due to *Actinomyces bovis,* while lesions of the soft parts—tongue, cheek, gum, palatal mucosa, skin, and lymphatic glands—are due to the actinobacillus. (2) The frequent involvement of the lymph glands in actinobacillosis; in actinomycosis the glands are swollen only as the result of secondary infection from open lesions. (3) Granules are rarely found in the glands in actinomycosis, very frequently in actinobacillosis. (4) In actinobacillosis the granules are paler in colour, and rarely calcified; in actinomycosis the granules are darker in colour and often calcified. (5) In actinobacillosis the granules consist of a central mass of detritus containing minute Gram-negative bacilli surrounded by long, radially disposed clubs; in actinomycosis recently formed granules contain a central Gram-positive mycelium, together with Gram-positive rods and coccoid forms, surrounded by short, radially disposed clubs; older granules may show a few Gram-positive bacillary and granular elements embedded in a Gram-negative matrix. (6) In actinobacillosis cultures reveal the presence of a small Gram-negative, aerobic cocco-bacillus; in actinomycosis a Gram-positive, branching, filamentous organism, often assuming rod forms in culture, not unlike *C. diphtheriæ,* is isolated under anaerobic conditions. During life the agglutination reaction may be of value. The serum of animals suffering from actinobacillosis frequently agglutinates the causative organism to a titre of 1/50 or over.

Actinobacillosis may affect *sheep*. According to Tunnicliff (1941), Christiansen in 1917 described a pyæmic infection of the heads of sheep due to an organism which he called *Bact. purifaciens*, but which was probably the actinobacillus. Thomas (1931), in South Africa, was the first to associate the disease in sheep with *Actinobacillus lignieresi*. The disease was relatively mild and occurred in animals fed on prickly pear. Lesions occur primarily in the lips, tongue, and cheeks, but the mandibular, retropharyngeal, mediastinal, and bronchial glands may also be affected. Single or multiple areas of granulation tissue are found on section, with burrowing irregular cavities containing sticky bright yellow pus, sometimes showing, on microscopical examination, ray-like formations and clubs. The disease in sheep has also been recorded by Ravaglia (1934) in Italy and Marsh and Wilkins (1939) in the United States.

Prophylactically, Lignières and Spitz (1902) found that segregation and killing of infected animals was the best procedure. Immune horse serum was employed in the treatment of some cases—though without conspicuous success. Iodide is said to be of much more value in the treatment of actinobacillosis than of actinomycosis.

So far as we know actinobacillosis is very rare in man. Ravaut and Pinoy (1911), Thompson and Willius (1932), Beaver and Thompson (1933), and Langeron (1941), have each described a case, but in no instance has the identification of the causative organism with *Actinobacillus lignieresi* been entirely satisfactory.

Pneumonia in Calves due to Actinobacillus actinoides.—Smith (1918, 1921) has described an epizootic broncho-pneumonia in calves, most common in the 2nd and 3rd months of life, characterized by areas of consolidation, focal necroses, and other lesions. From the lungs of a number of fatal cases in two separate outbreaks he isolated an organism which he called *B. actinoides* (see Chapter 11). In some cases it was present in pure culture, in others it was associated with *C. pyogenes*, *H. bronchisepticus*, or other organisms. On microscopical examination of the lungs, it was seen in the form of slender bacilli situated at the periphery of necrotic areas, aggregated into masses in the alveoli and alveolar ducts, or in the proliferating epithelium that occupied the smaller bronchioles. On coagulated horse serum, tiny whitish flocculi appeared in the water of condensation; these consisted of radiating filaments terminating in clubs. The organism was non-pathogenic to laboratory animals, but intratracheal injection into calves was sometimes followed by the appearance of small necrotic foci in the lungs, indistinguishable from those observed in the natural disease. This organism may be more closely related to *Actinomyces muris* (*Streptobacillus moniliformis*) than to the actinobacillus of Lignières and Spitz (see p. 381). Jones (1922) has isolated it from the pneumonic lungs of white rats.

CHAPTER 55

SWINE ERYSIPELAS, ERYSIPELOID, MOUSE SEPTICÆMIA, AND INFECTIVE MONONUCLEOSIS OF RABBITS

SWINE ERYSIPELAS

Introductory

Swine erysipelas is a disease affecting mainly pigs, and caused by the slender Gram-positive bacillus, *Erysipelothrix rhusiopathiæ*. Adolescent animals seem to be most frequently affected, but it occurs at all ages except during the first 3 months of life, when it is uncommon. The finer breeds of pigs are particularly susceptible. Four clinical types of the disease are described (Craig 1926). (1) The acute or septicæmic form. After an incubation period of 1 to 5 days, illness commences with prostration and high fever, anorexia, thirst, occasional vomiting, and conjunctivitis. Twenty-four hours later bright or dark red patches appear on the skin over the ears, snout, neck, abdomen, and inner sides of the forelegs. The mortality is about 80 per cent., death occurring usually in 3 or 4 days. (2) The urticarial form, or "the diamonds." This is a mild form accompanied by slight malaise and fever, and characterized by the eruption on the 2nd or 3rd day of well-defined, quadrangular or rhombic patches on the skin of the sides, back, and buttocks; the patches are slightly swollen, deep red or violet in colour, sometimes with a pale centre, from 1–5 cm. in diameter, and may become covered with dry crusts which are afterwards cast off. Recovery occurs in a few days; death is unusual. (3) The chronic or cardiac form. This may follow either of the previous types, or may arise independently. Warty vegetations develop on one of the heart valves, generally the mitral. Death may occur suddenly, or the animals may live for several weeks with symptoms of cardiac insufficiency. (4) The joint or arthritic form. This may follow the urticarial form, accompany the cardiac form, or arise independently. The joints of the limbs become enlarged, due to a synovitis; the animals are stunted, prefer the recumbent posture, and when induced to get up, walk in a stiff fashion on their toes with the back arched. This form is not usually fatal, but interferes with growth and fattening.

Morbid Anatomy.—In animals dying of the septicæmic form the spleen is enlarged, the lymphatic glands are congested, the gastric and intestinal mucosæ are reddened, and the lungs are œdematous; there are sometimes small hæmorrhages on the serous and mucous membranes and beneath the endocardium. The bacilli are found in small numbers in the blood, spleen, kidneys, and other organs, and in the secretions and excretions. In the cardiac form they are chiefly found in, and may be confined to, the vegetations on the valves.

Epidemiology.—Swine erysipelas is common in this country and throughout Europe. In America it has apparently been uncommon in the past, but according

to Breed (1938) it seems now to be spreading and becoming of increasing importance. It occurs particularly in valleys and low-lying districts, and during the summer and autumn months. In this country, as a rule, only a few pigs in a herd are affected, but on the Continent large epidemics may occur. The causative bacillus has also been found to be responsible for outbreaks of polyarthritis in sheep, joint-ill in lambs, and for occasional infections in horses, cattle, turkeys, and peacocks (see Beaudette and Hudson 1936, Paterson and Heatley 1938, Greener 1939), and erysipeloid (see p. 1285) and endocarditis (Russell and Lamb 1940) in man.

The natural disease in pigs is apparently due to intestinal infection, though infection by the skin appears possible. The bacilli have been found in the gall-bladders of animals that have recovered from the mild type of the disease (Pitt 1908*b*), and from the tonsils and intestinal mucosa of normal swine (Pitt 1908*a*, Tenbroeck 1920), so that carriers may play an important part in the spread of infection. The bacilli are very resistant to the changes associated with putrefaction, and may remain alive for months in carcases of buried animals (Lösener 1896); it is possible, therefore, that infection may occur by food or water contaminated with infected soil.

The disease can be experimentally reproduced in swine by inoculation with pure cultures (see Chapter 15).

Diagnosis.—The bacteriological diagnosis of swine erysipelas is made by microscopic examination of the blood during life, and of the blood and viscera after death, for the characteristic slender Gram-positive bacilli. If the organisms are too few to be seen microscopically, they may be cultivated on agar, in broth, and in gelatin stabs. If contaminated or putrefying material alone is available for examination, then the mouse inoculation test should be performed (see p. 398), or the material may be plated on 5 per cent. blood agar at pH 6·8 containing 1/100,000 sodium azide and 1/500,000 crystal violet (Packer 1943). The agglutination test may be of value, particularly in animals showing evidence of joint involvement. The antigen should be prepared from a smooth strain (see Schoening and Creech 1936). During life examination of the blood reveals a leucopenia, an increase in the mononuclears, and the presence of many atypical large mononuclear and lymphocytoid cells (Egehoj 1938).

Prophylaxis and Serum Treatment.—General prophylactic methods are similar to those for anthrax (see Chapter 76).

The routine vaccination of herds has been attempted by two or three different methods (Voges and Schütz 1898). Pasteur and Thuillier (Pasteur 1882, Pasteur and Thuillier 1883) were responsible for the first method. They stated that if the virus was passed through rabbits, it gradually lost its virulence for pigs; on the other hand, if it was passed through pigeons, its virulence was so exalted that the final passage virus was more virulent for pigs than even the most infectious products of pigs dying naturally from swine erysipelas. Their first vaccine, therefore, consisted of the avirulent rabbit passage virus; their second, which was given about 12 days after the first, consisted of the hypervirulent pigeon passage virus. Though it is quite impossible from the available statistics (Chamberland 1894) to assess the value of this method, there is a general consensus of opinion that so long as its use is restricted to the more resistant commoner breeds of pigs and to areas in which the disease is rife, it results in a general lowering of the mortality from swine erysipelas. When, however, it is used for protection of the less

resistant finer breeds, it frequently causes severe losses, amounting to 5 or 10 per cent. of the animals inoculated. For this reason its use has been very largely abandoned.

The methods now employed are those of sero-vaccination. In Lorenz's method (1893, 1894, 1896), a dose of immune serum is injected, followed after about 4 and 14 days by injections of living virulent bacilli. The serum provides a passive immunity, which is converted by the living vaccines, given subsequently, into an active immunity. In Leclainche's method the living vaccine is mixed with the serum, and the two are injected together. A second injection of vaccine alone is given 10 or 12 days later. Both these methods have been widely used, and appear to give satisfactory results. Both of them are open to the objection that living bacilli are introduced into the body, with the result that the animals may become healthy carriers of the disease. Immunization by the use of dead bacilli has not yet proved practicable (see Watts 1940).

In the actual treatment of swine that have already developed the disease the injection of 10–30 ml. of immune serum is recommended.

ERYSIPELOID

Infection of man with the bacillus of swine erysipelas was first described by Rosenbach in 1884 (see Rosenbach 1909). Though, according to Verge (1933), a cutaneous, an intestinal, and a generalized form of the disease may occur, the first type, usually referred to as "erysipeloid," is undoubtedly the commonest. It is met with in cooks, kitchen workers, butchers, and in those who handle fish, game, or cheese (Klauder 1926, 1932, 1938). Epidemics of the disease have been reported. Stefansky and Grünfeld (1930) describe an outbreak at Odessa affecting about 200 persons engaged in handling freshwater fish brought by sailing ships from the Dnieper and Bug; while Lawson and Stinnett (1933) in the United States report 247 cases of erysipeloid occurring among workers employed in sawing and polishing bones in the manufacture of buttons.

Klauder (1932) says that infection can invariably be traced to contact with animals, fish, shell-fish, dead matter of plant or animal origin, or matter derived from animals such as hides, pelts, bones, and manure. The organism usually gains access through injuries on the skin, including the bites of animals, fish, and crustacea. Where the organism comes from, however, is not so clear. Direct transmission to man from swine suffering from erysipelas appears to be uncommon (Bierbaum and Gottron 1929), but it is sometimes met with in veterinary students (Morrill 1939). Circumstantial evidence suggests that the organism is present in the slimy coating of various fish, but, though its isolation from this source has been recorded by Schoop (1936), there is some doubt as to whether the slime is infected under natural conditions or whether it becomes contaminated from the flesh during preparation for market. Fish can readily be infected experimentally (Hettche 1937, Brunner 1938). The organism is known to be very resistant to salting and putrefaction, and to survive for a long time outside the body.

However it reaches the skin, it gives rise, after an incubation period of 1–4 days, to an erysipeloid lesion characterized by a sharply defined, slightly elevated, purplish-red zone, which extends peripherally at the same time as it fades and desquamates centrally. The rash is accompanied by considerable swelling, itching,

burning, and pain. Regional lymphangitis and lymphadenitis may develop. Arthritis of the finger joints is not unusual. Relapses are common, and second attacks may occur. The milder forms last 2–4 weeks, but the disease may continue for months. Death rarely occurs, though Russell and Lamb (1940) have described one fatal case of endocarditis in which the organisms were isolated from the blood six times during life and from the endocardial vegetations at autopsy (see also Klauder, Kramer and Nicholas 1943).

The bacilli may be cultivated from the deep layer of an excised piece of skin. Alternatively tissue fluid may be obtained for culture by injecting saline into the skin at the border of the lesion, and re-aspirating it without withdrawal of the needle.

According to Klauder (1938) the most satisfactory form of treatment consists in a wet dressing of 12 per cent. ichthamol in alcohol. Formerly he (1926) favoured serum treatment, but he has discontinued this owing to the frequency of serum sickness, which may prolong the period of incapacitation. He reserves serum treatment for infections persisting for a month or more, for rapidly progressing infections, and for cases complicated by arthritis. In these he injects 100–150 ml. during the course of a few days, most of it intramuscularly, but some around the local lesion. Judged by mouse experiments sulphanilamide and sulphapyridine do not appear to be of value (Porter and Hale 1939).

MOUSE SEPTICÆMIA

Infection with *Ery. muriseptica*—an organism closely related to, if not identical with, *Ery. rhusiopathiæ*—gives rise to a natural infection in mice, which spreads readily among a herd of these animals, sometimes assuming epidemic proportions. The disease was originally described by Koch (1880) as *mouse septicæmia*.

The experimental disease produced in mice by the inoculation of *Ery. muriseptica* corresponds exactly with that produced by *Ery. rhusiopathiæ* (see p. 398.)

INFECTIVE MONONUCLEOSIS OF RABBITS

In 1926 Murray, Webb and Swann at Cambridge described a natural disease of rabbits characterized by a large-mononuclear leucocytosis, and caused by a small Gram-positive bacillus to which they gave the non-committal name *Bact. monocytogenes*. This organism, which has now been met with in a wide variety of animals, is often referred to as *Listerella*, but we have given our reasons (p. 399) for believing that it is closely related to the swine erysipelas bacillus, and should be called *Erysipelothrix monocytogenes*.

Young rabbits, between 1 and 3 months old, are chiefly affected. They are undersized, usually develop a very distended belly, undergo progressive emaciation, and often die suddenly. At post mortem the subcutaneous tissue is found to be œdematous, looking like jelly. Clear serous fluid is abundant in the pericardium, pleura, and peritoneum. As a rule the lungs are œdematous, and contain one or more red infarcts, the result of infected emboli. The liver is congested and sometimes contains small, round, pale-yellow or grey areas of focal necrosis, 1·5 mm. or less in diameter. The spleen is usually small, shrunken, pale pink, and rather

tough; but in acute cases, and in cases in which there is extensive necrosis of the liver, the spleen is normal in size or slightly enlarged, soft, and of a dark purple colour. The adrenals are sometimes soft and diffluent. The mesenteric lymph nodes are always enlarged and œdematous. Culture of the organism is difficult; it may be successful from the mesenteric nodes; the heart's blood is usually sterile.

The disease can be reproduced experimentally, and is often characterized by a monocytosis, and focal necroses of the liver (p. 398).

DISEASES IN OTHER ANIMALS CAUSED BY ERYSIPELOTHRIX MONOCYTOGENES

Space does not permit a detailed description of the numerous types of disease to which this organism may give rise. Suffice it to say that it has been isolated by Pirie (1927) from a plague-like disease of gerbilles in South Africa, by Gill (1933, 1937) from an encephalitic disease of sheep in New Zealand known as "circling," by Jones and Little (1934) from cases of bovine encephalitis in New Jersey, by Tenbroeck (1932) from a sporadic disease of chickens in New Jersey, by Burn (1933–34, 1935, 1936) in the United States and by Gibson (1935) in Scotland from meningeal infections in human beings, by Seastone (1935) in the United States and by Paterson (1937) in England from a generalized infection of fowls, by Schmidt and Nyfeldt (1938) in Denmark and by Pons and Julianelle (1939) in the United States from cases of infective mononucleosis in man, by Biester and Schwarte (1939) from meningo-encephalitis of sheep in Iowa, by Biester and Schwarte (1940) from meningo-encephalitis of swine, and by Paterson (1940) in England from abortion in sheep. (For further references see Paterson 1939.)

The relationship of this organism to glandular fever is discussed on page 1791.

CHAPTER 59

TUBERCULOSIS

In 1868 Villemin published his masterly study on the epidemiology of tuberculosis, and succeeded in transmitting the disease to animals by direct inoculation. Koch in 1882, after an investigation that will always remain as a classical example of thorough and accurate bacteriological technique, showed conclusively that the tubercle bacillus was the one essential cause of tuberculosis. The bacillus was resistant to all ordinary stains; but Koch succeeded in staining it by an alkaline solution of methylene blue, kept in contact with the tuberculous tissue for 24 hours. The bacillus would not grow on any ordinary medium; but he devised a new medium—inspissated blood serum—on which, after a delay of 10 days or so, growth first became apparent. Finally by a large series of inoculations with pure cultures of the bacillus, several generations removed from the primary one, he transmitted the disease to numerous animals of different species. Henceforward the demonstration of the bacillus afforded the sole infallible criterion for the diagnosis of all the manifold lesions of tuberculosis.

THE BACTERIOLOGY OF TUBERCULOSIS IN MAN

Tubercle bacilli may be divided by cultural and pathogenicity reactions into five types—human, bovine, murine, avian, and cold-blooded (see Chapter 16). Of these only the first two are found in natural infections of man. It is true that natural infections with the avian type have occasionally been described by continental workers, but the bacteriological evidence provided has not always been convincing. Feldman (1938), who reviewed the literature, could find a record of only 13 cases in which infection was probably due to the avian bacillus. In this country it was not found once in over 7,800 cases examined (Griffith 1938), but 2 cases have recently come to light.

The extensive work of the Royal Commission on Tuberculosis (Report 1911*a*), supplemented by the more recent findings of A. S. Griffith and of several other workers, have afforded us a knowledge of the frequency of tuberculosis in patients of different ages, which may be summarized in tabular form (Table 92). This table refers only to English cases. In Scotland the percentage of all forms of tuberculosis due to the bovine type is higher—often considerably so (see Griffith 1932*a*, 1934, Blacklock 1932, Griffith and Summers 1933, Blacklock and Griffin 1935, Munro and Scott 1936, Miller 1937, Griffith 1941). In Eire the information available suggests that the figures for non-pulmonary infections are much the same as in England (Mushatt 1940). Taking all ages into consideration, it will be seen that the majority of infections are due to the human type. About 1·5 per cent. of pulmonary and about 30 per cent. of non-pulmonary tuberculosis at all

ages in England and Wales appear to be caused by the bovine type. Infections of bovine origin are commonest during the first five years of life, and relatively uncommon in adults. The main organs affected by the bovine type are the gastro-intestinal tract and its associated lymphatic glands, particularly those of the cervical and mesenteric group. About 80 per cent. of cases of primary abdominal tuberculosis are due to the bovine type (Blacklock 1932, Griffith 1938); but secondary abdominal tuberculosis, which occurs most frequently as a late complication in pulmonary tuberculosis, is generally due to the human type. Lupus

TABLE 92

FREQUENCY OF BOVINE TUBERCLE BACILLI IN HUMAN BEINGS. ENGLISH STATISTICS. (Griffith 1938.)

Variety of Tuberculosis.	0 to 4 years.	5 to 14 years.	All ages.	
	Per cent. Bovine	Per cent. Bovine.	Number of Cases.	Per cent. Bovine.
Cervical gland	91·3	54·2	128	50·0
Lupus	58·4	44·4	191	48·7
Scrofulodermia	53·3	43·3	60	36·6
Bone and joint	29·5	19·1	554	19·7
Genito-urinary	—	—	23	17·4
Meningeal	28·1	24·5	265	24·6
Pulmonary	—	—	3,103	1·4
Miscellaneous	33·3	9·1	23	8·7

occupies a peculiar position; 48·7 per cent. of the strains are of bovine and 51·3 per cent. of human type. But generally both human and bovine strains are atypical; their cultural reactions conform to the standard of one or other type, but their virulence for animals is lowered. Since these atypical variants are found almost exclusively in lupus, it is probable that the degradation in virulence results from the sojourn of the organisms in the skin (Report 1911*b*). There is no evidence that it is due to the effect of light, as has been supposed, since organisms of lowered virulence are isolated both from exposed and unexposed areas. A. S. Griffith (1924) concludes that the changes occurring in the organisms cultivated from lupus lesions are not merely degenerative, but are the result of adaptation of the bacilli to sojourn in the skin. As a rule, by passage of atypical bovine strains through calves or rabbits, their full virulence is regained. Passage of atypical human strains through guinea-pigs or monkeys has not been successful in restoring their virulence (A. S. Griffith 1924). Atypical strains may be found in conditions other than lupus; thus in an investigation of 261 strains isolated from human cases of bone and joint tuberculosis Eastwood and F. Griffith (1916) encountered 10 atypical strains. Sometimes these atypical strains are found on further investigation to consist of a mixture of bovine and human bacilli (Report 1911*c*).

Approximately one-quarter of all cases of tuberculous meningitis and cerebral tuberculosis appear to be due to the bovine type (see Griffith 1932*b*, 1934, Blacklock and Griffin 1935, Griffith and Menton 1936). The proportion is greater in the lower than in the higher age groups.

Pulmonary tuberculosis has been generally held in the past to be due almost exclusively to the human type of bacillus. A. S. Griffith (1914), for example,

collected figures referring to 938 cases in which the causative organism had been typed, and found that in only six had a bovine type been isolated: in three of these it had been associated with a bacillus of human type. More recently, however, this conception has been challenged (see Munro and Griffith 1928, Griffith 1930, 1940, Griffith and Munro 1933, Cumming *et al.* 1933, Walker 1934, Griffith and Smith 1935, 1938, 1940, Tobiesen *et al.* 1935*a*, *b*, Lange, B. 1937). It has been shown that in Scotland and in Northern England an appreciable proportion of cases are due to infection with the bovine type (Table 93). The reason for the differences between different parts of the country is to be found in the higher incidence of tuberculosis in cattle in the northern half of Great Britain.

TABLE 93

FREQUENCY OF BOVINE TUBERCLE BACILLI IN PULMONARY TUBERCULOSIS IN DIFFERENT PARTS OF GREAT BRITAIN AND IRELAND.

(Cumming 1935, Griffith and Smith 1940, Griffith 1941, Griffith and Munro 1944, Cuthill and Lynn 1944.)

Area	No. of Strains Examined	Percentage Bovine.
Scotland, North-east	972	7·0
Rest of Scotland	1,797	5·1
England, North and Middle	3,219	2·0
Wales	201	1·0
England, South	989	0·6
Ireland	320	0·0

Summarizing, we may say that infections in this country with bovine tubercle bacilli occur mainly in children; in adults they are less common. The usual types of infection due to the bovine bacillus are glandular and alimentary tuberculosis, together with miliary tuberculosis and meningitis in infants and young children. In pulmonary tuberculosis, though it is very much less common than the human bacillus, it is sufficiently frequent to demand serious attention.

EPIDEMIOLOGY

Tuberculosis is an infectious disease that spares neither age, sex, race, nor nationality. The pulmonary form was described by Hippocrates, and spinal caries has been observed in the mummies of ancient Egypt (Smith, E., 1909). With the spread of civilization it became more rife; but now, in the more highly civilized countries of the world, it is declining. The main features of its epidemiology, as enumerated by Villemin (1868), are still generally true:

(1) Tuberculosis is uncommon in mountainous areas. It is comparatively rare in the mountains of Hungary and Styria, in the Carpathians, the Engadine, the Pyrenees, the high plateaux of Abyssinia and Armenia, in the Western Ghats and the Nilghiries, in the Himalayas, the Rockies, the Andes, and the high plateau of Mexico.

(2) It increases proportionately to the degree of crowding, and is especially common in the capitals, and great commercial and manufacturing towns.

(3) It attacks particularly persons who live in closed communities, such as prisoners, soldiers, and religieux.

(4) It spares those people who live in small communities, in the open air, or

in a savage or nomadic state. The wandering Arabs, for example, rarely contract tuberculosis; but it is common amongst the Arabs who have exchanged their tents for stone houses.

(5) It is very common among troops living in barracks, but is uncommon in the field and among troops who are not living in barracks. At the time at which Villemin wrote, the mortality from tuberculosis in the Army during peace time was from 5 to 12·5 per 1,000; in the field, however, the mortality was very much lower. As an example, he quotes the case of the Allied Armies before Sebastopol during the winter of 1854–5; even though they were living under most unhygienic conditions, and were subject to poor food, severe cold, and excessive fatigue, cases of tuberculosis were very rare

(6) Close contact in small, badly ventilated dwellings leads to the development of the disease.

(7) Though at one time unknown in Australia, New Zealand, North America, and parts of Polynesia, it has become a scourge in these countries since the advent of Europeans.

(8) Bovine tuberculosis, like human, increases with close contact and overcrowding; when it appears in a byre it generally attacks large numbers of animals.

All these facts bring tuberculosis into line with the other zymotic diseases.

Mortality from Tuberculosis.—Table 94 shows the annual mortality from tuberculosis of all forms and of the respiratory system in this country during the last 80 years.

TABLE 94

SHOWING THE ANNUAL MORTALITY PER 1,000 PERSONS LIVING IN ENGLAND AND WALES FROM TUBERCULOSIS. (STANDARDIZED DEATH RATES.)

Years.	Tuberculosis (all forms).	Tuberculosis of Respiratory System.
1851–55	3·638	2·890
1856–60	3·328	2·663
1861–65	3·316	2·625
1866–70	3·217	2·558
1871–75	2·956	2·327
1876–80	2·818	2·141
1881–85	2·558	1·922
1886–90	2·342	1·704
1891–95	2·138	1·504
1896–1900	1·912	1·337
1901–05	1·739	1·208
1906–10	1·556	1·082
[1] 1911–15	1·389	1·005
[1] 1916–20	1·359	1·009
1921–25	1·065	0·816
1926–30	0·922	0·721
1931–35	0·782	0·620
1936	0·658	0·526
1937	0·658	0·524
1938	0·603	0·477

[1] Mortality refers to civilians only.

It will be seen that the mortality has steadily declined since 1851—the first year for which standardized death rates are recorded. Several causes have been alleged for this decrease, such as better housing and sanitary conditions, improved

social habits, diminished drunkenness, higher standard of living, earlier diagnosis, segregation of advanced cases, sanatorium treatment, and the development of a racial immunity. It is extremely difficult to assess the importance of these factors. Greenwood and Wolff (1928) are of the opinion that greater weight must be ascribed to social, hygienic, and cultural improvements than to biological factors, such as the progressive increase in the resistance of the race through natural selection and acquired immunity.

Wolff (1935) points out that the tuberculosis mortality has declined more in the industrialized States of Europe than in those which are still mainly agricultural. The reason for this, he believes, is that the standard of living and general social hygiene are on a higher level in the industrially developed than in agricultural countries. Much the same thesis is put forward by Baskett (1931), who maintains that in all civilized countries the phthisis mortality is inversely correlated with the level of real wages. That biological factors are also operating, however, is almost certain. Ostenfeld, Heitmann, and Norlyk (1931), for example, point out that in Sweden during the past century there has been a centrifugal spread in the frequency of the disease. A hundred years ago the highest death rate from tuberculosis was in Sodermanland, where now it is lowest; while Norrbotten, which 100 years ago was relatively free from the disease, is now specially affected. The suggestion is that the resistance of a population in which the disease has been prevalent for some generations is greater than that of a population coming into contact with tuberculosis for the first time. Further evidence in support of this thesis will be found in a later section dealing with tuberculosis in native races.

Among the social factors that are of importance great stress is laid by Wolff (1936*b*) on diet and by Hart and Wright (1939) on housing. There is little exact knowledge on the influence of *diet*. Shortage of first-class proteins was regarded by Faber (1938) as being largely responsible for the rise in tuberculosis mortality that occurred in western Europe during the war of 1914–18. Experimentally there is some evidence that animals fed on a plentiful diet are more resistant to infection than those on a meagre diet, and that Vitamin A deficiency may lower their resistance (see Robertson 1934, Clausen 1934, and Chapter 54). Kon and Maddock (1938), however, were unable to confirm the importance of Vitamin A in the protection of pigs against experimental infection. Osborn and Gear (1940) have pointed out that animals, like the dog and the rat, which can synthesize their own Vitamin C, are more resistant than those, like man, the monkey, and the guinea-pig, which cannot. During the war of 1914–18 the death rate from tuberculosis in German cities, which was only 1·57 per 1,000 in 1913, rose in 1918 to 2·87. In Warsaw by 1917 it had reached 8·4 per 1,000, and in Belgrade, as the result of the military occupation and want of food, it rose to the enormous figure of 14·0 per 1,000 (Dublin, see Opie 1929). In the second world war there was again an increase in mortality. The factors that may have played a part in this rise in Great Britain are discussed in a report by the Medical Research Council (Report 1942).

Without in any way minimizing the desirability of active public measures against tuberculosis, it may be pointed out that the decline in the tuberculosis death rate in this country set in long before the establishment of hospitals, sanatoria, or dispensaries for the treatment of patients suffering from the disease, indicating that the underlying social, economic, and biological causes were able by themselves to effect a considerable reduction in the mortality from tuberculosis in the absence of any *ad hoc* public health interference.

Some Factors affecting the Mortality from Tuberculosis.

Occupation.—Occupation is of importance. In this country the mortality from pulmonary tuberculosis is below the average for all males in fishermen and coal-

miners, but is high in stone and slate quarrymen, in cutlers, file-makers, earthenware manufacturers, and highest of all in the Cornish tin-miners. All trades, in fact, in which the men are exposed to the inhalation of particles of metallic or stone dust, particularly dust containing silica, have a high mortality rate from pulmonary tuberculosis. Both experimental and field work have shown the predisposing action of silica towards tuberculosis (Gye and Kettle 1922, Kettle 1924, 1930, Hart and Aslett 1942).

Though not strictly relevant to occupation, it may be pointed out that tuberculosis mortality is much higher in *mental* patients, particularly in schizophrenics, than in the general population. For example, according to Deegan, Culp and Beck (1942), the death rate from tuberculosis during 1937–39 in mental institutions in New York State, outside New York City, was 6·18 per 1,000 as against 0·51 per 1,000 in the population as a whole, that is, over 12 times as high.

Age and Sex.—We have no space to analyse the age and sex incidence fully. Table 95 shows the high mortality of the disease in the 0–5 age group; the fall during the period of adolescence; the great increase in mortality, especially in women between the ages of 15 and 30; and the high mortality in men between the ages of 40 and 55 from what is known as the late adult type of tuberculosis.

TABLE 95

DEATHS FROM TUBERCULOSIS IN 1934 IN ENGLAND AND WALES CLASSIFIED ACCORDING TO AGE AND SEX.

Age Group.	Tuberculosis (all forms).		Tuberculosis of Respiratory System.	
	Males.	Females.	Males.	Females.
All ages	17,448	13,434	14,734	10,948
0–1	242	171	39	18
1–5	693	615	83	65
5–10	337	349	69	59
10–15	335	414	101	214
15–20	901	1,412	688	1,198
20–25	1,843	2,194	1,604	1,983
25–30	1,748	1,905	1,570	1,757
30–35	1,678	1,485	1,527	1,369
35–40	1,494	1,118	1,371	1,022
40–45	1,473	900	1,378	796
45–50	1,707	776	1,624	705
50–55	1,662	624	1,576	546
55–60	1,402	510	1,316	435
60–65	927	382	889	333
65–70	637	289	580	229
70–75	232	168	209	131
75–80	102	80	85	63
80 and upwards	35	42	25	25

During the present century a great change has come over the age and sex distribution of tuberculosis. Reference to Fig. 271 will show that during last century and the first decade of the present century the mean annual death rate per 100,000 living was highest in infancy and early childhood, while in 1933 it was highest in the 20–25 age group.

The fall in the death rate during the early years of life has been most striking. This is almost certainly attributable to some extent to the much greater care now

exercised in infant welfare, and to the more general provision of pasteurized milk (see Drolet 1930). It may be noted that the highest tuberculosis mortality in children occurs during the 1–2 age group, and is due to various types—respiratory, meningeal, abdominal, miliary, and chronic disseminated. Meningitis alone is responsible for about 50 per cent. of the total deaths during the first 10 years of life.

The death rate in young adults, on the other hand, has undergone much less alteration. Most of the deaths in this group are due to pulmonary tuberculosis,

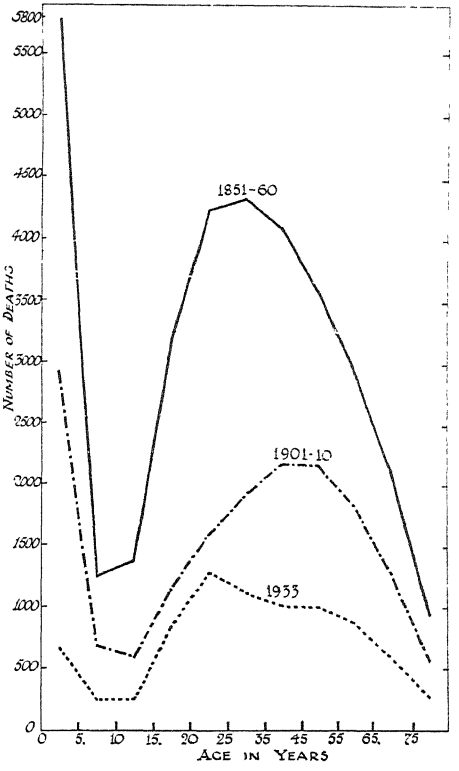

FIG. 271.

Death rates per million from tuberculosis (all forms) at ages. England and Wales 1851–60, 1901–10, and 1933.

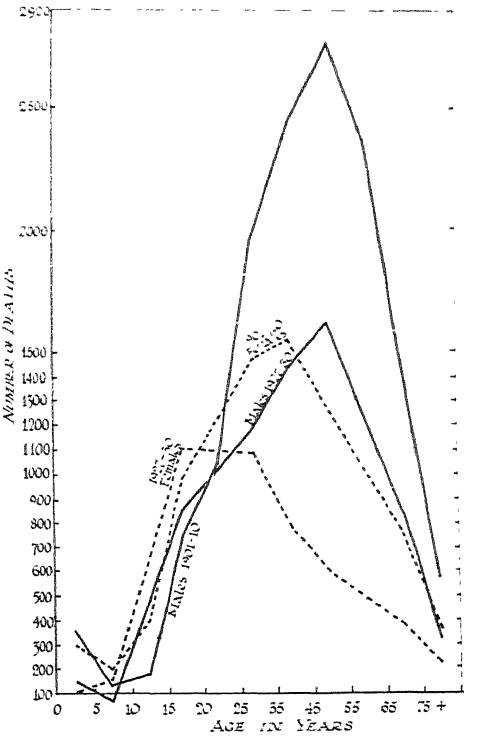

FIG. 272.

Death rates per million from pulmonary tuberculosis at ages for each sex. England and Wales 1901–10 and 1927–30.

and as Fig. 272 shows, the death rate from this form is much higher in females than in males in the 10–30 age group. Indeed the female pulmonary tuberculosis death rate in the 20–25 age group is practically identical with that in the first years of the century.

After the age of 30 the male pulmonary tuberculosis death rate increases, till in the 45–55 age group it is nearly three times that of the female death rate. The reasons for these differences are not apparent, and though they are often lightly attributed to changes in the general mode of life of young women during the present century, and to the greater strain of competitive existence among men, the reasons

are undoubtedly complex, and we shall do well to refrain from attempting to simplify them unduly. We may note that the changes in the age and sex distribution of tuberculosis are not confined to this country, but are reflected in greater or less degree in the statistics of many other European countries and of the United States of America (see Dow and Lloyd 1930, Drolet 1930, Whitney 1931, MacNalty 1932, Hill 1936, Hart and Wright 1939).

Race and Civilization.—Certain races seem to be more susceptible than others; thus the Negroes in North America suffer much more severely than the white population. In eight of the great cities of the United States, the mortality from tuberculosis in 1920 amongst the white population varied from 0·794 to 1·216 per 1,000

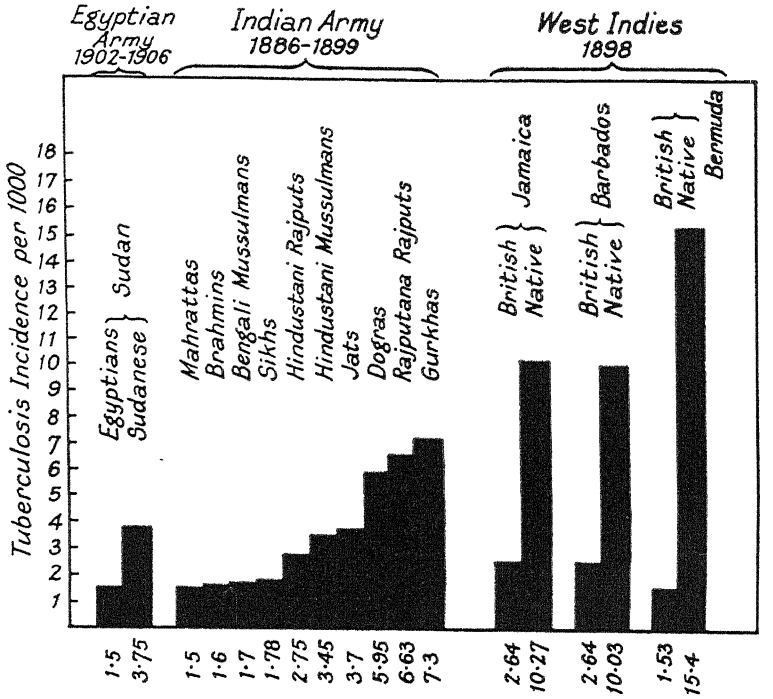

FIG. 273.
(After Cummins.)

living, whereas amongst the coloured population it varied from 2·855 to 4·405 per 1,000 (Mossell 1923). Jews, on the other hand, are said to have a high resistance (see Arnould 1936). In Fig. 273 is represented the incidence per 1,000 from tuberculosis amongst different races living under military conditions.

It will be seen that the differences in mortality between different races are very striking. There are so many factors influencing the distribution and mortality of tuberculosis that it would be unjustifiable to conclude that all these differences are due to a lower *genetic* resistance of the coloured than of the white races. The environment in which the two races live, the level of personal and social hygiene, the nature of the diet, and numerous other factors vary widely, and we know of no data in which the mortality of the disease is compared in coloured and

white subjects living under identical conditions and exposed to the same risk of infection from birth upwards (see Krause 1928, Johnson and Myers 1933, Scott 1935).

In primitive peoples living in their native countries tuberculosis either does not occur or is comparatively uncommon. This freedom from tuberculosis appears to be not an expression of the inherent resistance of man living under natural conditions, but is rather due to the lack of opportunity of infection with the tubercle bacillus. Once this organism is imported—generally by the advent of white Europeans—the disease may spread rapidly, provided the environmental conditions are suitable. The same happens when primitive peoples leave their native country and take up residence in a civilized area. Many of them become infected, contract a severe form of the disease, and die.

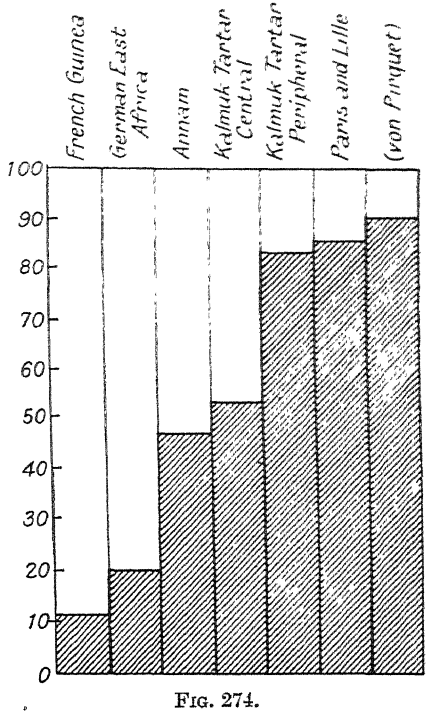

FIG. 274.

Comparative percentages of positive cutaneous tuberculin reactions in primitive and civilized peoples. (After Cummins.)

This sequence of events has been noticed by several competent observers. Cummins (1908) found that the death rate from tuberculosis amongst the Sudanese in the Egyptian Army was considerably higher than amongst the Egyptians (Fig. 273). In their native country tuberculosis was rare; but when they were brought into contact with more civilized peoples, they proved to be very susceptible to the disease. Metchnikoff, Burnet, and Tarassevitch in 1911 reported that the nomadic Tartar Kalmuks 50 years ago were practically free from tuberculosis; but that under the influence of increasing contact with the Russians, they were becoming more and more infected by the disease. In the central parts of the Steppes cases were uncommon, but at the periphery, where contact with civilization occurred most freely, tuberculosis was very frequent. Coleman, reporting on the North American Indians, brought evidence to show that tuberculosis was unknown before the advent of Europeans. With the advance of civilization, however, it has become increasingly common. The toll of life levied by the disease in some tribes is enormous; in 1896, for example, amongst the Oglalas the incidence of tuberculosis was 148·7 per 1,000, and the death rate 24·88 per 1,000. Borrel's (1920) observations on the Senegalese troops during the war of 1914–18 are of interest. In the villages and interior of Senegal tuberculosis is rare; but when the Senegalese troops were brought to France, large numbers of them developed tuberculosis. The longer their stay was in France, the higher was the incidence of tuberculosis amongst them. After 1 year's stay the mortality from tuberculosis was 2 per 1,000; after 3 to 4 years' stay it was 16 per 1,000. In 1918 the case incidence was as high as 36·1 per 1,000. (For references to these and other observations see Cummins 1911–12, Westernhoeffer 1911, Bushnell 1920.) A study of the tuberculin reaction (see p. 1300) shows that in primitive peoples the proportion of positive reactors is low; but that the more they come into contact with civilization, the greater is the proportion of reactors (Fig. 274).

Not only, however, is the mortality from tuberculosis high amongst primitive peoples brought into contact with civilization, but the type of disease tends to differ from that usually met with in civilized countries. Instead of the localized, slowly spreading, ulcerative type of phthisis, the disease often pursues a rapid course, fatal in a few weeks to a few months. Pathologically, the glands at the site of infection—generally the tracheo-bronchial group—are enormously enlarged and caseating, and there are miliary tubercles throughout the body. The tissues seem to be devoid of resisting power; there is no fibrosis, no limitation of the lesions, and no attempt at healing.

This acute type of tuberculosis recalls the type that is met with in infants of civilized peoples. A fairly high proportion of infants who become infected with the tubercle bacillus develop an acute, fatal disease, generally of the miliary type. That this is true is shown by the combined evidence of the tuberculin test, the mortality statistics, and post-mortem findings (see p. 1303). After the first year of life in civilized peoples, tuberculosis assumes a subacute or chronic course, and the miliary spread is seen only as a fatal termination, not as a primary manifestation of the disease. But in uncivilized races brought for the first time into contact with tuberculosis, the acute, fatal, miliary type is seen quite commonly even in adults.

At the present time there must be very few native races left that have not had some degree of contact with civilization. Tuberculin surveys carried out in recent years have shown that most native races are now undergoing a process of tuberculization, and it is to be expected that the acute miliary type so often met with in peoples brought into contact with tuberculosis for the first time will gradually give way to the more chronic types characteristic of civilized peoples. See Paneth (1928), Scott (1929, 1935), Editorial (1929), Duchêne (1929), Goodale and Krischner (1930), Kleine (1930), Schwetz (1930), Schwetz *et al.* (1930), Grasset and Perret-Gentil (1930), Whitney (1931), Pinner and Kasper (1932), Report (1932*b*), Review (1933), Sauvan (1935), Rodríguez Pastor *et al.* (1935), Long (1935), Cochrane (1937), Carmichael (1938), and numerous papers in the *American Review of Tuberculosis* and the *Tropical Diseases Bulletin* during 1936 to 1945.

Heredity.

The part played by heredity in predisposing to tuberculous disease is still an open question. Before the discovery of the tubercle bacillus, the disease was believed to be inherited. It is difficult to decide, however, from the observation that the disease tends to run in families, how much is due to inferior genetic resistance and how much to household exposure to infection. The milder nature of the disease in old-established civilizations than in primitive peoples coming into contact with civilization for the first time may be due to a process of weeding out by natural selection of the less genetically resistant members of the population. Explanations of this sort, however, though plausible, cannot carry conviction. As has already been pointed out (p. 1296) only a comparison of the morbidity and mortality of the disease in, for example, coloured and white subjects living under identical conditions and exposed to the same risk of infection from birth upwards can give us a satisfactory answer. Recent observations on animals and on human beings, however, do suggest fairly strongly that inherited resistance to tuberculosis varies widely.

Carmichael (1938), for example, found that the incidence of tuberculosis among the long-horned Hamitic cattle belonging to the Bahima people of Ankole was much higher

than among the humped Zebu cattle of Uganda, even though the environmental conditions appeared to favour the Hamitic variety. Though these animals lived almost entirely in the open air, 80 per cent. of them reacted to tuberculin, as against less than 1 per cent. among the Zebu cattle. Besides being resistant to natural infection, the Zebu cattle proved almost entirely refractory to experimental inoculation. Lurie (1941) studied six inbred families of rabbits, and found a wide difference in their response to infection with bovine tubercle bacilli, whether inhaled as the result of natural contact or inoculated parenterally. In the animals of the most resistant family the lung disease tended to be localized, and the primary focus progressed slowly, became encapsulated, and underwent cavitation. In the animals of the most susceptible family little or no localization occurred, and the disease was of the rapidly progressive generalized type. It is important to point out that in all the animals the disease was progressive; the chief difference lay in the rate of progression. It was also found that when the bacilli were administered artificially by the respiratory tract, the difference between the families was noticeable only when the dose was small; above a critical level the rabbits of even the most resistant family succumbed rapidly to the infection. No one factor seemed to be responsible for the differing resistance of the different rabbit families. Several factors were apparently implicated. Thus it was found that low skin permeability to the injection of Indian ink, rapid and intense development of allergic sensitivity, and rapid and high production of antibodies were associated with resistance; whereas high skin permeability, slow and feeble development of allergic sensitivity, and tardy and poor production of antibodies were associated with susceptibility (see also Lurie 1944*b*).

A careful study by the twin family method on the susceptibility of human beings to tuberculosis by Kallmann and Reisner (1943*a*, *b*) goes far towards confirming the conclusions reached from animal experiments. In co-operation with the tuberculosis hospitals and clinics in the State and City of New York a study was carried out on 308 complete twin families, comprising 616 twin partners, 930 full siblings (both parents in common), 74 half-siblings (one parent in common), 688 parents and 226 marriage partners of twin patients. Among the 308 twin pairs there were 78 monozygotic (uniovular) and 230 dizygotic (binovular) pairs. When a twin developed tuberculosis in an institution or was admitted to a hospital or clinic, the other twin was examined. The first twin was termed the index case. The investigation was restricted to pulmonary tuberculosis in twins 15 years of age or over. Corrected tuberculosis morbidity expectation rates were worked out to estimate the chances of a relation of a twin index case developing manifest tuberculosis; they were as follows: Marriage partners 7·1 per cent.; half-siblings 11·9 per cent; parents 16·9 per cent.; full siblings 25·5 per cent.; dizygotic twins 25·6 per cent.; monozygotic twins 87·3 per cent. These figures indicate that the chances of developing tuberculosis increased in proportion to the degree of blood relationship to a tuberculous index case. Monozygotic twin partners, it will be noted, were 3·5 times as likely as dizygotic twin partners to develop tuberculosis if the co-twin had tuberculosis. These differences could not be explained on the basis of greater exposure of monozygotic twins to infection. It was further observed that the morbidity expectation among siblings and dizygotic twins was about twice as high for the descendants of tuberculous parents as for descendants of non-tuberculous parents. Further studies along these lines in other parts of the world will be awaited with interest.

The Frequency of Tuberculosis.

In this country tuberculosis is a notifiable disease, and it might be thought that the number of notified cases would afford a fair estimate of the frequency of the

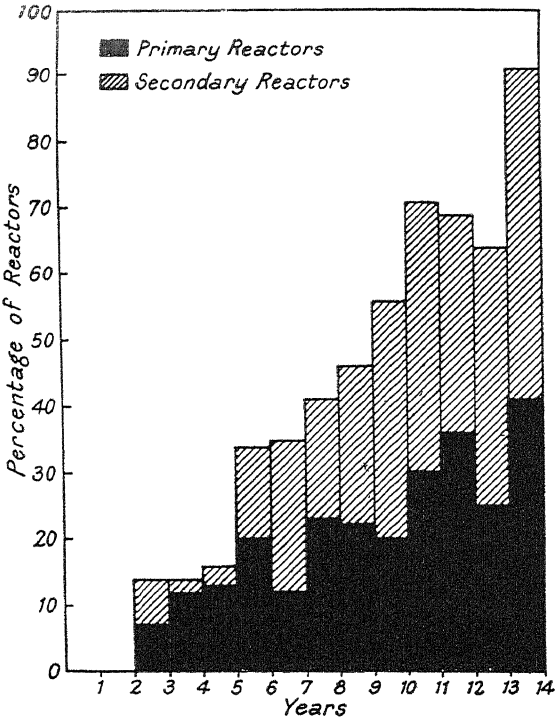

FIG. 275.

(Modified from von Pirquet.)

disease. In fact, however, this is not so. For various reasons —medical and social—large numbers of cases are not notified, and the resulting figures sometimes scarcely exceed the deaths. They are in fact so unreliable that, since 1931, the Registrar-General has ceased to publish them in his Annual Report. Neither the morbidity nor the mortality statistics afford any adequate idea of the prevalence of tuberculous infection. To obtain a satisfactory idea of this, it is necessary to resort to three other sources of information, namely, the tuberculin test, post-mortem statistics, and X-ray examination.

Latent Tuberculosis as revealed by the Tuberculin Test. —The tuberculin test as used by von Pirquet (1907) consists in placing a drop of tuberculin on the forearm and a drop of 50 per cent. glycerine adjacent to it as a control. With a small lancet a scratch is made through each of the drops. A positive reaction is denoted by the appearance within 24 or 48 hours of a bright red papule, at least 5 mm. in diameter at the site of inoculation of the tuberculin; later the colour becomes dark red, and the lesion disappears in about a week. This may be called a primary positive reaction. In some persons, however, the reaction is delayed for a few days, or occurs only after a second inoculation a week later—torpid or secondary reaction. From a large series of tests, it would appear that a primary positive reaction is evidence of the existence in the body of a comparatively recent tuberculous lesion, which may or may not be actively progressing. A torpid or secondary reaction is believed to indicate the existence of an old tuberculous lesion in the process of healing. Complete failure to react is regarded as evidence that the person has never come into contact with tuberculosis, or that healing has occurred. Von Pirquet's original technique has been modified by many subsequent observers, some of whom lay stress on the advantages to be gained by using varying dilutions of tuberculin, and so obtaining quantitative results.

Using this test, von Pirquet (1909) examined 1,134 clinically non-tuberculous infants and children in the Escherich Clinic at Vienna. The patients belonged to the lower classes, and were probably more heavily infected with tuberculosis than were the children of the higher social classes. It is important to remember in interpreting the results, given in Table 96 and Fig. 275, that tuberculosis was

at the time of the investigation exceedingly rife in Vienna; it is not justifiable, therefore, to regard them as generally applicable to every urban population.

TABLE 96

SHOWING THE PERCENTAGE OF CHILDREN WHO REACTED TO THE TUBERCULIN TEST IN VIENNA. (Modified from von Pirquet.)

Age	0–1	1–2	2–3	3–4	4–5	5–6	6–7	7–8	8–9	9–10	10–11	11–12	12–13	13–14
No. of cases	388	89	75	87	62	66	61	39	72	45	44	45	39	22
Primary positive	0	0	7%	12%	13%	20%	12%	23%	22%	29%	30%	36%	25%	50%
Torpid or secondary positive	0	0	7%	2%	3%	14%	23%	18%	24%	36%	41%	33%	39%	41%
Total reactors	0	0	14%	14%	16%	34%	35	41%	46%	65%	71%	69%	64%	91%

The figures for the older age groups are rather small; but it is clear that by the age of 10 years about 70 per cent., and by the age of 14 probably over 90 per cent., of children were infected with tuberculosis. It will be noticed that torpid or secondary reactions were uncommon under 5 years, but gradually increased with age; this may be taken to indicate that quite a high proportion of children between 5 and 14 had old, and probably healing, tuberculous foci.

Similar investigations undertaken by various workers have shown that in the large cities of Europe, such as Paris, Vienna, and Prague, about 20 per cent. of children are infected at the age of 2, 55 per cent. at 5, and 90 per cent. at 15; of adults 97 per cent. are infected (Mantoux 1910, Calmette *et al.* 1911).

The von Pirquet test is now being gradually displaced by the *graded intradermal* or *Mantoux test.* In surveying a given population it is usual to inoculate 0·1 ml. of a 1/10,000 dilution of old tuberculin (O.T.) intradermally into the forearm. A positive reaction is characterized by the development within 12–72 hours of an area of œdema or induration at least 5 mm. in diameter; many workers insist on a minimal diameter of 10 mm. Erythema of varying extent is usually present, but by itself does not constitute a positive reaction. If the reaction is negative after 48 hours, a second injection is given, using 0·1 ml. of a 1/100 dilution. Lower dilutions are now seldom employed, since the reactions to them are often non-specific. In the past an injection with a 1/1,000 dilution was commonly used for negative reactors to the 1/10,000 dilution; but experience has shown that it is safe to proceed directly to a dilution of 1/100. A positive von Pirquet test corresponds approximately to a reaction to the intradermal inoculation of 1/1,000 tuberculin. Since the use of a 1/100 intradermally may detect 5–15 per cent. more reactors than the 1/1,000 dilution (Hetherington *et al.* 1929, Dow and Lloyd 1931, Hart 1932), it is clear that the graded intradermal test is more sensitive than the von Pirquet test. Old tuberculin is now often replaced by the purified protein derivative of tuberculin (P.P.D.) described by Seibert (1934, 1941*a*). For routine purposes this is given usually in a first dose of 0·00002 mgm. and a second dose of 0·005 mgm., corresponding approximately to doses of 0·002 mgm. and 0·5 mgm. of O.T. (Long, Aronson and Seibert 1934). There is reason to believe, however, that the second dose is too strong and may give a certain proportion of false positive reactions (Long and Seibert 1937, Furcolow *et al.* 1941). The two products generally give similar reactions in survey work (see Plunkett and Siegal 1937, Doig *et al.* 1938); but sometimes there is a disagreement which, according to Seibert and Du Four (1940), may be due to the presence in O.T. of non-specific substances that augment the specific reaction (see also Vollmer and Ripps 1943). Though in this country it is usual to refer to the actual dilution injected, in the United States the dose is expressed

in milligrams of tuberculin; by this notation 1 mgm. of tuberculin is supposed to be contained in 0·1 ml. of a 1/100 dilution.

Some of the results obtained during recent years by the graded intradermal test are reproduced in graphical form in Fig. 276.

It is apparent that in the large industrial cities of Europe and America most children are infected with tuberculosis by the time they reach 18 years of age, but in rural areas infection is much less frequent. Since only a comparatively small proportion of reacting children develop clinical tuberculosis or die of the disease, it is clear that in the majority of them the infection must remain latent. This deduction is of fundamental importance to a proper understanding of the mechanism of immunity in tuberculosis.

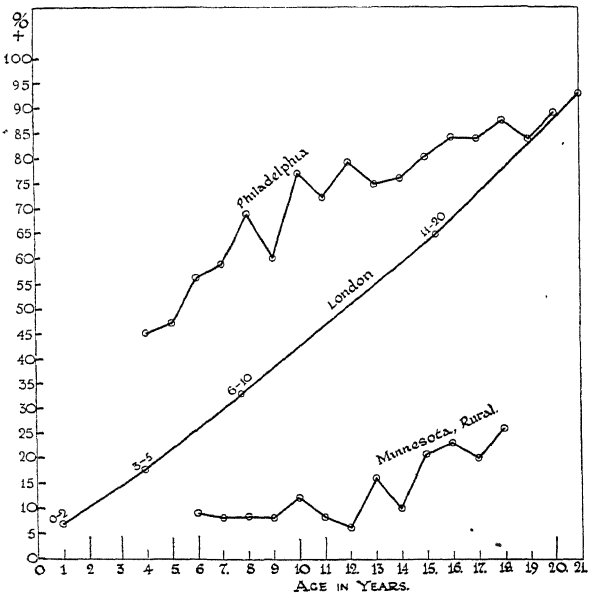

Fig. 276.

Percentage of children and adolescents reacting to the intradermal inoculation of old tuberculin.
(1) Philadelphia school children reacting to 1/100 dilution (Hetherington *et al.* 1934).
(2) London hospital children reacting to 1/100 dilution (Hart 1932).
(3) School children in wealthy rural community in Minnesota reacting to 1/1000 dilution or to von Pirquet test (Slater and Jordan 1932).

It has been shown by a number of workers that children brought up in contact with open cases of tuberculosis react to tuberculin at a much earlier age than normal children. Fig. 277, taken from Dow and Lloyd (1931), shows that over 70 per cent. of children of such parents react positively by the age of 5 years. In children brought up in contact with tuberculous parents having a negative sputum the proportion of tuberculin-positives is little higher than in normal children.

Further references to tuberculin surveys will be found in papers by Scheel (1929) Myers (1930), Myers *et al.* (1934), Brink *et al.* (1933), Cummins and Evans (1933), Drolet (1934), van den Berg (1936), and in numerous papers in the *American Review of Tuberculosis*, the *American Journal of Public Health*, and the *Bulletin of Hygiene* during the last few years.

Latent Tuberculosis as revealed by Post-mortem Statistics.—It is one of the commonest experiences of the post-mortem room to find evidence of tuberculosis in persons who presented no clinical evidence of the disease during life, and who died from some other cause. The lungs and lymphatic glands are the organs that are usually affected. For purposes of classification we may divide tuberculosis as found at autopsy into three classes: (1) Fatal tuberculosis, in which the disease has been directly responsible for death. (2) *Latent active tuberculosis*, in which advancing, generally caseous, lesions are found, but which do not appear to be the immediate cause of death. (3) *Latent inactive tuberculosis*, in which the lesions are apparently healed and often calcified.

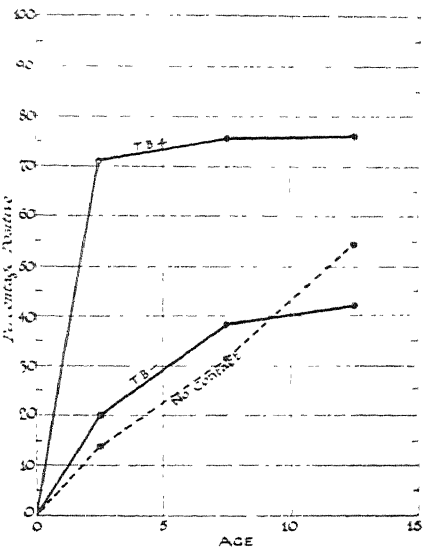

FIG. 277.

Percentage of contact and non-contact children reacting to the intradermal tuberculin test at ages. (Dow and Lloyd 1931).

In 1900 Naegeli published the results of an investigation at Zürich, made to determine the frequency of tuberculous lesions in subjects coming to autopsy. A very careful examination was made of every cadaver, and all doubtful lesions were subjected to microscopic examination. Caseation and calcification were accepted as evidence of tuberculosis; the oblique, distorted indurations at the lung apex were considered tuberculous or not, according to histological examination and the presence of other tuberculous lesions in the body. Table 97 and Fig. 278 show his general results.

The surprising observation was made that, in adults, 93·11 per cent. showed evidence of tuberculosis. In his first series of 136 adults, only 113 or 83·1 per

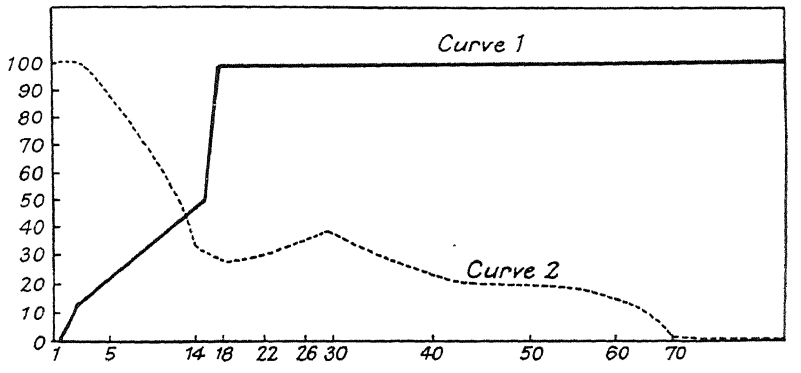

FIG. 278.

Curve 1 = frequency of tuberculous lesions in every 100 autopsies of the same age group.
Curve 2 = frequency of fatal tuberculosis in relation to all cases of tuberculosis.
(After Naegeli.)

TABLE 97

MODIFIED FROM NAEGELI (1900), SHOWING THE FREQUENCY OF TUBERCULOSIS (TB.) OF ALL FORMS IN POST-MORTEM SUBJECTS AT ZÜRICH.

	Autopsies.	Tb. not found.	Tb. found.	Percentage Tb.	Of Tb. Patients.			
					Died of Tb.	Percentage.	Non-lethal Tb.	Percentage.
Children 0–18 years .	88	73	15	17·04	11	73·3	4	26·7
Adults 18 years and over	420	29	391	93·11	110	28·13	281	71·84

cent. were found to be tuberculous; but in his last series of 284 adults, probably owing to his greater experience, as many as 278 or 97·9 per cent. were found to be tuberculous. It will be observed that of the children who showed tuberculosis, 73·3 per cent. had died of the disease (Table 97). In other words, latent or non-lethal tuberculosis is very much commoner in adults than in early life. Naegeli came to the following conclusions: (1) Tuberculosis is very infrequent in infancy, reaches 96 per cent. by the 18th year, and 100 per cent. by the 50th year. (2) In infancy 100 per cent. of cases of tuberculosis are fatal; at 18 years of age 29 per cent. are fatal; 38 per cent. at 30 years; 22 per cent. at 40 years; 10 per cent. at 65 years, and practically none at 70 years. (3) Latent active tuberculosis is uncommon in children; reaches 33 per cent. at puberty; 40 per cent. at 30 years; and falls to 25 per cent. in later years. (4) Latent inactive or healed tuberculosis is infrequent before 18; reaches 25 per cent. in the 3rd decennium; 40 per cent. in the 4th decennium; and 75 per cent. in the 70th year. (5) The disposition towards fatal tuberculosis is therefore highest in infancy; falls to puberty; rises towards 30 years; and later falls again. After 18 years, immunity increases more or less proportionally to age.

A similar, but more extensive series of autopsies, was reported on by Burkhardt in 1906. The material examined came from the Dresden-Friedrichstadt Hospital, and to a less extent from the Kgl. Frauenklinik. It is important to notice that the autopsies were made on the working-class population. Since the mortality from tuberculosis amongst patients of this class was 35 per cent., while amongst the general population of Dresden it was only 13–14 per cent., it is clear that the results he obtained are not representative of the population as a whole. His figures are shown in Table 98.

TABLE 98

MODIFIED FROM BURKHARDT (1906), SHOWING THE FREQUENCY OF TUBERCULOSIS (TB.) OF ALL FORMS IN POST-MORTEM SUBJECTS AT DRESDEN IN 1900–01.

	Autopsies.	Tb. not found.	Tb. found.	Percentage Tb.	Of Tb. Patients.			
					Died of Tb.	Percentage.	Non-lethal Tb.	Percentage.
Children 0–18 years .	190	118	72	38	35	48·6	37	51·4
Adults 18 years and over	1,262	113	1,149	91	466	40·6	683	59·4

These figures agree fairly well with Naegeli's. The chief differences are that the incidence of tuberculosis in children is higher, the mortality from tuberculosis in children is less, and that in adults is higher than in Naegeli's figures. Both agree in showing that in persons of 18 and onwards the incidence of tuberculosis exceeds 90 per cent.

Burkhardt gives a very instructive table recording the incidence of latent tuberculosis in the different age groups (Table 99).

TABLE 99

SHOWING THE FREQUENCY OF LATENT TUBERCULOSIS IN PERSONS CLASSIFIED ACCORDING TO AGE.

Percentages reckoned on every 100 persons of the same age coming to autopsy.

Age Group.	Latent Active Tb.	Latent Inactive Tb.
	Per cent.	Per cent.
1–5	9	4
5–14	25	11
14–18	5	24
18–30	12	26
30–40	14	34
40–50	18	38
50–60	19	44
60–70	21	50
70–80	22	57
80–90	22	61

From this table it is seen that, though the percentage of persons with latent active tuberculosis does not vary greatly in the different age groups, the percentage with latent inactive or healed tuberculosis increases progressively with age.

The general inferences which appear to be justified by these results are as follows:

(1) The great majority of persons living in civilized countries, and particularly in urban communities, have been infected with some form of tuberculosis by the time they attain adult life.

(2) Between 10 and 20 per cent. of persons of all ages living in such communities are suffering from some focus of tuberculous infection which, though latent, is active.

(3) A large proportion of these latent active lesions must heal spontaneously, since evidence of healed tuberculosis increases with age. In parenthesis, it may be pointed out that apparently healed, even calcified, tuberculous lesions may not infrequently contain living tubercle bacilli (Opie and Aronson 1927, Feldman and Baggenstoss 1938, 1939, Saenz and Canetti 1938).

It must be understood that Naegeli's and Burkhardt's figures refer to all forms of tuberculosis. For the frequency of pulmonary tuberculosis, see p. 1314 and Tables 102 and 103 (p. 1314). It would be wrong to assume that the figures of these two workers represent the frequency of tuberculous lesions at the present time. The forty or more years that have elapsed since their observations were made have witnessed a considerable reduction in both the morbidity and the mortality from tuberculosis, so that it is by no means justifiable to say now, as it was then, that practically every adult is infected with the tubercle bacillus. Landé and Wolff (1941), for example, working among a semi-rural population in Maryland,

found that only 48·4 per cent. out of 128 persons over 20 years of age coming to autopsy showed evidence of tuberculous infection.

In Scotland, Blacklock (1932, 1935, 1936) has contributed valuable information on the frequency of tuberculous infection in children. He carried out post-mortem examinations at the Royal Hospital for Sick Children, Glasgow, on 1,800 children under 13 years of age dying from various causes during the years 1924–34. He found (1) that practically all children under 2 years of age showing tuberculous lesions had actually died of tuberculosis, whereas in children 4–13 years of age only about 75 per cent. had died of this disease, and (2) that the percentage of positive tuberculin reactors in the first two years of life was nearly the same as the percentage incidence of tuberculous lesions found at autopsy, indicating again that at this age practically all children who became infected died of the disease. These figures refer to a low social class in Scotland in which tuberculosis is undoubtedly a very severe disease, and it would be unjustifiable to conclude that they are valid for all classes and for all countries. Indeed there is considerable evidence to the contrary (Rosenberg and Kereszturi 1937, Price 1938). With the progressive decline in tuberculosis mortality that is occurring in Europe and America, primary lesions are being increasingly observed in adults. Many of them appear to run a more benign course than those in infancy (Terplan 1934, Wallgren 1938).

In considering the *fatality of tuberculous infection in early life*, it must be remembered that the type of case seen by Naegeli, by Burkhardt and by Blacklock, was not representative of the whole infantile population, but merely of that portion of the infantile population which showed symptoms of disease of sufficient severity to demand admission to hospital. If an equal number of apparently healthy infants could have been examined, it is quite conceivable that many would have shown latent tuberculous lesions. All our figures hitherto have been selective. The diagnosis of tuberculosis in infancy is extremely difficult, and only advanced and fatal cases are recorded. The result is that we have come to believe that infection in infancy is usually fatal. That this conclusion is wrong is shown very clearly by the observations made at Lübeck on the infants who were vaccinated by the mouth during the first few days of life with the B.C.G. strain (see p. 1337). The vaccine had by mischance become contaminated with virulent human tubercle bacilli and a large number of the infants became infected (Report 1935*b*). Out of 251 vaccinated infants, 72 died of tuberculosis, 5 died of other causes, while 174 were alive two to three years later. It is probable that all the surviving children had been infected to a greater or less extent, and radiographical examination actually showed the presence of calcified mesenteric glands in 127 of them. It is interesting to note that practically all cases that developed a primary lung lesion died, while the majority, which had primary alimentary lesions, survived.

We may conclude tentatively that tuberculous infection in infancy is often liable to cause death, particularly if it occurs by the respiratory tract. Infection is, however, by no means uniformly fatal. Provided the environmental conditions are good, and exposure to infection is not too severe or repeated, it seems probable that latent lesions may result of a type similar to those met with in later years.

Latent Pulmonary Tuberculosis as revealed by X-ray Examination.

In recent years X-ray examination of the chest has come to play an important part in the diagnosis of pulmonary tuberculosis, since it is possible by this means to detect lesions before clinical manifestations have developed. In several countries

surveys are now being made to determine the frequency of pulmonary lesions in different classes of the population. Table 100, taken from Hetherington, McPhedran, Landis and Opie (1929), affords an example of the type of result obtained.

It refers to the roentgenological examination of school children, both white and

TABLE 100

15–19 . . .	1,060	20·1	1·9	0·2	1·0	0·5	23·7

coloured, in Philadelphia, Pa. The figures are selective, and refer almost exclusively to those children who reacted to an intradermal injection of 0·1 ml. of 1 10,000 tuberculin. It will be noted that in the older children over 20 per cent. showed pulmonary or associated glandular lesions. Of these, 0·7 per cent. actually had clinical symptoms of disease. The distinction between the childhood and the adult type of pulmonary tuberculosis may be neglected for the moment; it will be referred to later (p. 1314).

What proportion of latent lesions progress to a stage at which they give rise to clinical tuberculosis is at present unknown. It is quite clear from the post-mortem evidence that has already been given that many of them must remain latent or gradually retrogress. Special *ad hoc* surveys to follow the history of children with such lesions are at present being made, and it is hoped that in a few years' time we shall be in a better position to answer this question.

Numerous other figures might be quoted to show the high frequency of latent active and overt tuberculosis in medical students and nurses, both of whom are often exposed to an unusually high risk of infection (see Heimbeck 1927, 1932, 1933, Ross 1930, Hetherington *et al.* 1931, 1935, Herman *et al.* 1932, Shipman and Davis 1933, Geer 1934, Kramer 1934, Stiehm 1935, Jacobs 1938, Soper and Amberson 1939, Hart, Hilton and Morland 1940, Hedvall 1940, Hetherington and Israel 1940, Brahdy 1941, Israel, Hetherington and Ord 1941, Alt, Barth and Day 1941, Hastings and Behn 1941, Lyght 1942, Ridehalgh 1942, Daniels 1944). Reference may also be made to similar surveys conducted by X-ray examination, sometimes in association with the tuberculin test, in school children and other classes of the population (see Chadwick 1927, Opie *et al.* 1929, Hewitt and Cutts 1932, Martin *et al.* 1934, Fellows 1934, Rouvillois 1934, Harrington *et al.* 1935, Weber *et al.* 1935, Hetherington, Israel and Kreitz 1938, Pope, Sartwell and Zacks 1939, James 1939, Douglas 1939, Hutchinson and Pope 1940, Galbraith 1941, Trail 1942, Banszky 1942, Clive 1943, Brooks 1944, Marshall 1945).

Frequency of Tuberculosis in relation to Degree of Exposure to Infection.

It has already been pointed out that in children exposed to contact with patients suffering from open tuberculosis the proportion reacting to tuberculin reaches a high figure in the early years of life (see Fig. 277, p. 1303). Observations by numerous workers on families containing one or more members with a positive sputum have now shown that the children in these families have a much higher morbidity and mortality rate from tuberculosis than children in families with sputum-negative patients, and still more so than children in families completely free from tuberculosis. In this country Cox (1929) analysed the histories of 1,486 children under 5 years of age in Lancashire exposed to contact in the home with open tuberculosis. In these children the death rate from non-pulmonary tuberculosis was 9 times greater in the 0–1 year age group, 14 times greater in the 1–2 age group, and 19 times greater in the 2–5 age group than that of a control child population in the County of Lancaster. The excess deaths, it may be noted, were mainly due to tuberculous meningitis. In households containing one or more persons suffering from tuberculosis but having a negative sputum, the death rate of the exposed children was rather greater than that in control children, but the differences were not statistically significant. Cox's figures have received general confirmation from the observations of Turner in Worcestershire (1931).

In the United States even more convincing evidence is available from the extensive observations of Opie (1928–29, 1935) and his colleagues (see Opie and McPhedran 1935, McPhedran and Opie 1935), and of such workers as Evarts, Potter, and Dunn (1934) and Stewart, Gass, Puffer, and Williams (1943). The following figures furnished by Opie, McPhedran, and Putnam (1935), which refer to the development of pulmonary tuberculosis, are of interest in showing not only the much greater frequency of the disease in subjects exposed to open cases of tuberculosis, but also the proportion developing pulmonary tuberculosis in relation to the age of exposure.

(1) Of persons first exposed between 0 and 9 years to contact with sputum-positive patients, 9·92 per cent. of those living 12–14 years after the beginning of exposure had acquired pulmonary tuberculosis, whereas among those exposed to contact with sputum-negative patients, only 1·97 per cent. subsequently developed the disease.

(2) Of persons first exposed between 10 and 14 years to contact with sputum-positive patients, 20 per cent. of those living 10–14 years after the beginning of exposure had acquired pulmonary tuberculosis, whereas none of those exposed to contact with sputum-negative patients had acquired the disease.

(3) Of persons first exposed after 15 years of age to contact with sputum-positive patients, 9·68 per cent. had acquired pulmonary tuberculosis, while the corresponding figure for persons exposed to sputum-negative patients was 6·86 per cent.

On the basis of these observations we may conclude with Opie and his colleagues that the spread of tuberculosis in the community is, in great part, the result of slowly progressive household epidemics, which often lead to the transmission of the disease by contagion from one generation to another.

TUBERCULOSIS OF HUMAN ORIGIN. METHODS OF INFECTION

Tubercle bacilli may gain entrance to the body by various routes.

The possibility of *congenital* infection seems to be very small. Sitzenfrey (see Ghon *et al.* 1925) examined 26 placentas from tuberculous mothers, and found tuberculous lesions in 7 of them ; on the basis of these results Moll (see Ghon *et al.* 1925) argues that there are two types of infantile tuberculosis : (1) an early form due

to hæmatogenous infection of the fœtus from the placenta; and (2) a later form, of respiratory origin, occurring in extra-uterine life. The former type he would regard as definitely congenital. But Ghon, Kudlich and Winternitz (1925), who investigated this subject, found no evidence to support the occurrence of congenital infection; in 87 infants investigated at autopsy they found a primary focus of disease indicative of post-natal infection; in none of them was a picture found corresponding to Moll's early form.

Tubercle bacilli may gain access to the body by *direct inoculation*, as by an infected needle or knife, or through an abraded pustule (von Eiselberg 1887). Cases of direct inoculation of tuberculosis are uncommon, but are seen occasionally in butchers, post-mortem attendants, and laundresses.

Infection may occur by passage of the bacilli through the various mucous surfaces of the body, but except for that part of the mouth and pharynx which is more or less common to the respiratory and alimentary tracts, this route of infection is probably of minor importance.

Pulmonary Tuberculosis.—We now come to the much-discussed question of the mode of infection in the most common of all tuberculous diseases—pulmonary tuberculosis. There are two main hypotheses: the first, advocated by von Behring and by Calmette and his colleagues, maintains that infection occurs primarily through the mucosa of the alimentary tract; the second, advocated by Cornet, Flügge, and in this country by A. S. Griffith and Cobbett particularly, maintains that infection occurs primarily by the respiratory tract. We must consider briefly the evidence in favour of each of these opposing views.

Von Behring in 1904 advanced the hypothesis that the pulmonary tuberculosis of adolescent and adult life is the end-result of an infantile infection contracted by the absorption through the mucosa of the alimentary tract of bacilli ingested with the food. In childhood the infection is manifested by caseous glands, particularly cervical and mesenteric; in adult life by caseous apical tuberculosis of a chronic type. This hypothesis was supported to some extent by the work of Calmette and Guérin (1905).

Pregnant goats were injected into each udder with 0·02 gm. of a fresh bovine culture. Severe lesions resulted, confined to the udder, and proving fatal in 40–60 days. From one such animal two kids were raised; one of these was killed in a sickly condition on the 45th day, and the other died on the 51st day after birth. This second animal, besides showing enlarged mesenteric glands at necropsy, also had miliary tubercles in the lungs; the peribronchial glands were normal. In a second experiment, performed on two kids 5 days old, they delivered 0·05 gm. of a fresh bovine culture directly into the stomach; two or four doses were given. One of the animals died about 10 weeks later; post mortem, the mesenteric glands were greatly enlarged; the lungs were riddled with tubercles; and the peribronchial and posterior mediastinal glands were very large and were filled with caseous tubercles. In a third experiment, the same procedure was adopted on adult goats. When killed 7 to 9 weeks later, these animals showed little or no swelling of the mesenteric glands; the peribronchial and posterior mediastinal glands were not affected; but the lungs were tuberculous. On the basis of these results they conclude that, in the great majority of cases, pulmonary tuberculosis is contracted, not by inhalation, but by ingestion of dust or products containing tubercle bacilli; the bacilli pass through the mucosa of the alimentary tract and are carried to the lung. They dissent, however, from von Behring's suggestion that adult pulmonary tuberculosis is due to the slow evolution of an intestinal infection contracted in infancy: on the contrary, they think that adults develop pulmonary tuberculosis more easily than children after intestinal infection;

children are better protected by their lymph-glandular system. Dust, they consider, is infective, not because it is inhaled, but because it is swallowed.

Further experiments by Calmette and Guérin (1906*a*, *b*) showed that the lungs might become diseased after intra-œsophageal infection of heifers and cows with bovine bacilli. Vallée (1905) found that the bronchial glands of young calves might be infected by feeding the animals on tuberculous milk, but he failed by this method to produce lesions in the lungs. One further piece of evidence adduced by Calmette in favour of the intestinal origin of infection in tuberculosis is the analogy presented by glanders. He states that it is impossible to produce the usual pulmonary type of glanders in horses by intratracheal injection of the bacilli; but if the glanders bacilli are given to the horse in its drinking water, pulmonary glanders consistently results. He concludes (1920) that in all susceptible animals, including man, tuberculosis in its manifold varieties of localization—glandular, pulmonary, alimentary, etc.—results in the great majority of cases from an infection, primarily lymphatic, then hæmatogenous, having its origin in the absorption of tubercle bacilli by the digestive tract—principally by the buccal, pharyngeal, and intestinal mucosæ.

It will be realized that the evidence adduced by Calmette is derived entirely from experiments on animals. There is no doubt that pulmonary lesions may follow the alimentary infection of goats and heifers; but the observations of White and Minett (1941) in the calf suggest strongly that the bacilli reach the lungs not through the intestine but by aspiration down the trachea during the process of feeding or intra-œsophageal inoculation. When the bacilli were introduced directly into the duodenum, so as to exclude regurgitation and aspiration, the lungs never became infected.

The evidence in favour of the respiratory hypothesis, on the other hand, is derived largely from observations made on human patients; it depends partly on the anatomical distribution of the lesions, and partly on the types of infecting bacilli.

The workers on the Royal Commission, and subsequently A. S. Griffith, Eastwood, and F. Griffith, examined in all 260 children under 12 years of age who had died of tuberculosis. From 32 of these children, bovine tubercle bacilli were isolated. In all the cases infected with bovine bacilli in which there were lesions, the anatomical evidence pointed definitely to the alimentary tract as the portal of entry of the bacilli (Griffith, A. S., 1925*b*). In these cases the mesenteric glands were the most severely affected regional lymphatic glands; the bronchial glands either were not macroscopically tuberculous, or showed disease of slighter degree and in an earlier stage. The anatomical picture of the disease in children from whom human tubercle bacilli were obtained was less uniform than in the bovine cases. They could be divided into three groups: (1) In the first group the respiratory tract was evidently the portal of entry; the bronchial glands were the most severely affected regional lymphatic glands; the mesenteric glands either not being affected, or showing more recent disease obviously secondary to the thoracic disease. (2) In the second group, both the bronchial and the mesenteric glands were severely affected, and there was nothing to indicate that one set of glands had been infected previously to the other. Probably infection had occurred simultaneously by both the respiratory and the alimentary tracts. (3) The third group was a small one, and contained those cases in which the alimentary tract was the sole portal of entry of the human bacillus; the distribution of disease was the same as in the bovine cases.

From these results the following conclusions were drawn: (1) The path of infection of the *bovine* tubercle bacillus is almost exclusively the alimentary tract. (2) The chief portal of entry of the *human* tubercle bacillus is the respiratory tract. (3) Primary abdominal tuberculosis due to the human tubercle bacillus is rare.

We know that pulmonary tuberculosis is, with few exceptions, due to the human tubercle bacillus ; and we have evidence, founded on post-mortem results, to show that the human tubercle bacillus generally enters the body by the respiratory tract. We may therefore conclude that in most cases of pulmonary tuberculosis infection has occurred by the respiratory and not by the alimentary tract.

Further evidence of the inhalation hypothesis is obtained by considering the types of tubercle bacilli that are found in different situations of the body (Table 101).

It will be seen that 98 per cent. of infections of the lungs and 95 per cent. of infections of the bronchial glands are due to the human type of bacillus. On the other hand, as many as 50 per cent. of abdominal and 46 per cent. of cervical gland infections are due to the bovine bacillus. If, as von Behring and Calmette suppose, pulmonary tuberculosis were due to bacilli that had gained access to the body through the alimentary tract, it would be reasonable to expect that about 50 per cent. of infections of the lungs and bronchial glands would be due to the bovine bacillus. This is clearly not the case. The figures in the table afford no evidence that the bacilli pass downwards from the cervical, or upwards from the mesenteric, glands to invade the bronchial glands and lungs ; on the contrary, the fact that bovine bacilli are uncommon in these organs suggests that infection must occur by some other route, namely the respiratory tract.

TABLE 101

SHOWING THE PROPORTION OF BOVINE AND HUMAN INFECTIONS IN DIFFERENT VARIETIES OF TUBERCULOSIS. (Modified from Cobbett 1922.)

Type of Tuberculosis.	Type of Tubercle Bacillus. England. All Ages.	
	Human.	Bovine.
	Per cent.	Per cent.
Pulmonary	97·9	2·1
Bronchial glands	94·5	5·5
Abdominal	50	50
Cervical glands	54	46

If the lungs are infected by the respiratory tract it is not difficult to understand why bacilli of the human type should almost invariably be found in pulmonary tuberculosis. The most common source of infection with the bovine type is milk, and this is invariably ingested by the mouth ; human tubercle bacilli, on the other hand, are often present in the air in the form of cough-spray or in dust from dried sputum, and are in a suitable state to be inhaled. The almost invariable presence of human bacilli in tuberculous lungs strongly suggests that infection occurs by inhalation.

Another argument in favour of the respiratory mode of infection in pulmonary tuberculosis is based on a comparison of the frequency of mesenteric tuberculosis in this country and America. Examining 67 young British adults, Opie (1925) found healed tuberculous lesions of the mesentery in 27 per cent.—a finding that he ascribes to the high incidence of bovine tuberculosis in this country. In America, where bovine tuberculosis is much less frequent, lesions of the mesentery are uncommon in human beings. Yet both in this country and in America, pulmonary tuberculosis is very frequent. If the lungs were infected from the alimentary tract, pulmonary tuberculosis should be much commoner in this country than in America. But this is not so.

Finally we may refer to the very careful studies of Ghon (1916) in Vienna, and of Opie (1917*a*, *b*, 1924*a*, *b*, 1925) in America, on the anatomical distribution of the lesions

in the pulmonary tuberculosis of childhood. Dissection of the lungs after death, aided by preliminary examination with the X-rays, showed that the primary lesion occurred in the substance of the lungs, and that the bronchial glands were infected only secondarily. This clearly points to the respiratory tract as the portal of infection. If the bacilli reached the lungs from the alimentary tract *via* the lymphatics, the bronchial glands should show the primary, and the lungs the secondary lesions.

From these various sources of evidence we conclude that, with the exception of those cases of miliary tuberculosis in which the lungs have been infected from the blood stream, the vast majority of cases of pulmonary tuberculosis are due to infection by the respiratory tract. In the light of recent work a further exception should perhaps be made for those cases of tuberculosis of bovine origin in which the pulmonary disease is apparently secondary to lesions in the glands. Further work is required on the exact mechanism of infection in these cases, but there is no reason to modify substantially the general conclusions that have just been reached.

Dust and Droplet Infection.

Accepting the inhalation hypothesis, we are faced with the problem of how the bacilli gain entrance to the respiratory tract. The evidence brought to bear on this problem is so extensive that we can give nothing more than a brief outline of the conclusions drawn from it. According to Cornet (1889), the chief source of infection is the *dust arising from dried sputum*. Examining 140 specimens of dust taken from various situations—chiefly hospitals, public buildings, and the private rooms of tuberculous patients—he found tubercle bacilli in 40 of them. He believed that tubercle bacilli may remain alive and virulent in dust for 3 or 4 months. He maintained that, apart from his sputum, a patient suffering from pulmonary tuberculosis is harmless. The main objections to this view are: (1) For the tubercle bacilli to be set free by the desiccation of sputum the air must be absolutely dry; if it is at all moist, complete desiccation does not occur. In Europe, at any rate, the atmospheric conditions during most of the year are unfavourable for complete desiccation. (2) During the process of drying there is evidence that the tubercle bacilli, especially if exposed to sunlight, are liable to die (Heymann 1901, Mayer, E., 1921, Caldwell 1925, Eidinow 1927).

According to Flügge (1899) and members of his school (Moeller 1899, Heymann 1901, Findel 1907, Ziesché 1907, Hollmann 1924), the tubercle bacilli gain entrance to the respiratory tract in the form of *minute droplets* expelled from the mouth and nose of patients suffering from open pulmonary tuberculosis. Buchner showed that bacteria suspended in a very fine spray could be conveyed through several metres of rubber tubing, even when only a light current of air was used. Laschtschenko found that sprayed tuberculous sputum carried tubercle bacilli in suspension over a considerable distance when propelled by an air-current of only 3 mm. per second. By taking suspensions of *Chr. prodigiosum* into his mouth, he showed that organisms were expelled to a slight extent during speaking, to a greater extent in coughing, and to a still greater extent in sneezing. Numerous workers have found that tuberculous patients when coughing expel droplets containing tubercle bacilli; these droplets are projected for varying distances, but not further as a rule than 1½ metres. Guinea-pigs placed about half a metre from the mouth of tuberculous patients, and exposed freely to their cough-spray, not uncommonly contract tuberculosis.

To this view Lange and Keschischian (1925) raise objections on the ground that the droplets expelled during the act of coughing are so large that they rapidly fall to the ground.

Using a Buchner spray they found that droplets of an aqueous solution of eosin of 200 μ or over in diameter remained in suspension for a few seconds; droplets of 20 μ and under for a few minutes, and droplets of only a few μ for 1 to 3 hours. But since the droplets expelled in coughing are said to be fairly large, they conclude that primary lung infection by droplets must be uncommon. Their measurements of the size of the droplets were made on glass slides; but as Strauss (1926) points out, the diameter of a droplet that has settled on a slide is not the same as its diameter when suspended in the air; in fact it is about three times as great. He concludes, from a series of measurements he made, that the diameter of droplets of sputum suspended in the air is about 50–250 μ, the majority being 70–85 μ. Droplets of this size can probably remain in suspension for a minute or two, and are consequently liable to be inhaled.

W. F. Wells (1934) notes that the falling velocity of a small droplet is proportional to the square of its diameter. He calculates that the time taken for droplets of various sizes to fall 2 metres—rather over the height of a tall man—is as follows: droplets with a diameter of 0·1 mm. 6 seconds, of 0·01 mm. 10 minutes, of 0·001 mm. 16·6 hours. But as these droplets fall they evaporate, and the rate of evaporation is inversely proportional to the square of the diameter. Water droplets with a diameter of 1 mm., falling in unsaturated air at a temperature of 18° C., will evaporate in 165 secs., those with a diameter of 0·1 mm. in 1·7 secs., those with a diameter of 0·05 mm. in 0·4 secs. Droplets expelled from the human mouth in coughing, sneezing or loud talking will clearly not evaporate so rapidly as droplets of water, since they contain in solution substances that tend to retain water; but the same general relations will hold. The larger droplets, those of 0·1 mm. or over in diameter, will tend to behave as above. They will settle rapidly, and while settling, and for some little time after, they will retain their droplet form. Smaller droplets will behave quite differently. They will remain suspended in the air for much longer periods; but, since they soon lose their water by evaporation, they will quickly cease to be droplets and will become what the author refers to as "droplet nuclei," *i.e.* the bacteria or other particles contained in the droplet together with any substances in solution, the whole in a desiccated or semi-desiccated state. The physical properties of these "droplet nuclei" are not precisely calculable, but all analogies suggest that they might remain suspended in air for a very considerable time. They would, moreover, be carried long distances by air currents.

This wide difference in behaviour between large and small droplets is, as the author emphasizes, of obvious significance in relation to the spread of infection. The term "droplet infection," as commonly employed in medical literature, should be regarded as applying to the spread of infection by droplets larger than 0·1 mm. in diameter. It is spread of this sort that will usually be measured in experiments where Petri dishes are exposed at various distances from a coughing or speaking person. Spread by droplets smaller than 0·1 mm. in diameter and by their nuclei is best described as "air-borne" infection. It will obey quite different laws and may, under certain conditions, be of great epidemiological importance. (See also Wells and Stone 1934, Wells and Wells 1936, and Chapter 91.)

From animal experiments there is no doubt that tubercle bacilli, whether in the form of dry dust, of moist droplets, or of droplet nuclei, can penetrate the respiratory passages and reach the lung (Lange and Nowoselsky 1925, Wells and Lurie 1941, Glover 1944). It is probable therefore that Cornet and Flügge are both right. The only question is which mode of infection is the more common—dust or droplet infection. Considering that in this country the atmospheric conditions are seldom suitable for the formation of absolutely dry sputum, whereas the opportunities for droplet infection must be extremely common in such situations as trains, 'buses, trams, theatres, meeting-places, and crowded rooms of all sorts, droplet infection, including air-borne infection by droplet nuclei, is probably of far greater importance

than infection by sputum. The discussion may seem to be of purely academic interest; but from the standpoint of preventive medicine it is of considerable importance. Injunctions against spitting are numerous; but if Flügge's view is correct, it is clearly of far greater value to educate the public never to cough or sneeze without putting a handkerchief in front of the mouth. In this country a start has been made along these lines. It is to be hoped that the result will lead to a diminution in the risk of contracting not only pulmonary tuberculosis but all diseases that are spread by the respiratory tract. Some idea of the degree of infection of the air may be gathered from the observations of Pressman (1937) in the United States who, by the simple expedient of exposing four dishes containing saline in the corners of a room for one week, was able to demonstrate the presence of tubercle bacilli in 87 per cent. of 55 samples taken from four tuberculosis hospitals and sanatoria.

Pathogenesis of Pulmonary Tuberculosis. Childhood and Adult Types.

Evidence has already been brought to show that pulmonary tuberculosis of adults is usually due to respiratory infection. We must now consider the different types of pulmonary disease that occur in childhood and adult life, and decide whether adult pulmonary tuberculosis is a continuation or recrudescence of the childhood form, or is due to a re-infection in later years.

As previously stated, Ghon (1916) came to the conclusion that the primary lesion in tuberculosis of infants and children occurs in the substance of the lungs, and that secondary to this infection the adjacent lymphatic glands become involved. Opie (1917*a*, *b*, 1924*a*, *b*, 1925), besides confirming this conclusion, carried out a large series of examinations on the lungs of persons of all ages who had died of non-tuberculous diseases. The pulmonary tuberculosis of children up to 10 years of age was, he found, essentially of a *focal* type; the lesions were situated in any part of the lungs, and were accompanied by caseation or calcification of the regional lymphatic glands. In older children, and in adults, two types of tuberculous lesions were found: focal lesions, similar to those in infants and young children; and apical lesions, situated at the apex of the lungs, and not accompanied by caseation of the regional glands. Focal lesions developed in early childhood, and increased in frequency throughout life, as can be seen by reference to Table 102.

TABLE 102

FREQUENCY OF HEALED TUBERCULOUS LESIONS (FOCAL OR APICAL) IN THE LUNGS OF PERSONS IN ST. LOUIS, DYING OF DISEASES OTHER THAN TUBERCULOSIS.

Age.	Frequency.
2–5 years	42·8 per cent.
5–10 „	45·5 „
10–18 „	55·5 „
18–30 „	83·3 „
30–50 „	91·3 „
50–70 „	93·3 „

Apical tuberculous lesions were not encountered in young children, but increased with advancing age (Table 103).

TABLE 103

FREQUENCY OF LATENT APICAL TUBERCULOSIS IN 50 AUTOPSIES ON PERSONS IN ST. LOUIS, DYING OF DISEASES OTHER THAN TUBERCULOSIS.

Age.	Frequency.
18–30 years	16·7 per cent.
30–50 „	13 „
50–70 „	26·7 „
70 and over	50 „

The question naturally arises: Have the apical lesions of adult life developed from the focal lesions of childhood? Opie brings evidence to disprove this: (1) apical tuberculosis is more common in later life when the focal lesions of childhood have in most instances completely healed; (2) in adults the focal lesions of childhood are almost invariably calcified and healed, and no longer contain living tubercle bacilli (Opie and Aronson 1927), whereas the apical lesion is relatively fresh and caseous; (3) in at least half of the cases examined, the focal lesion was in one lung and the apical lesion in the opposite lung. Moreover, the characters of active pulmonary tuberculosis in childhood and in adult life are different.

Characters of Active Pulmonary Tuberculosis of Childhood.	*Characters of Active Pulmonary Tuberculosis of Adults.*
1. No particular localization.	1. Apical localization.
2. Hilum glands involved.	2. Hilum glands not involved.
3. Little or no tendency to cavity formation or deposition of fibrous tissue.	3. Tendency to cavity formation and deposition of fibrous tissue within the lung substance.
4. Rapid course.	4. Chronic course.
5. Similar to infection of normal guinea-pig.	5. Similar to infection of tuberculous guinea-pig.

We may conclude therefore that, though in most cases of apical tuberculosis a focal lesion is present, the apical lesion is not an extension of the focal disease. In other words, the phthisis of adults is not the result of tuberculosis acquired in childhood.

Additional evidence in support of this view has been advanced by Opie (1928–29, 1935) and by Opie, McPhedran, and Putnam (1935). Following up children exposed to contact with open tuberculosis at some time between birth and 9 years of age, these workers found that the maximum proportion of infiltrating lesions of the childhood type detectable by X-ray examination was reached at about 3 years of age, after which it fell gradually to zero by 11 years of age. On the other hand, latent apical lesions of the adult type were not seen before 4 or 5 years of age, but after this they rose progressively as the age of the child increased. In other words, the two types of lesions behaved as if they were entirely unrelated. Further observations showed that children first exposed to infection after 15 years of age usually developed the typical adult apical type of pulmonary disease.

All these findings suggest that the pulmonary tuberculosis of adults is not usually a continuation of childhood disease, but is due to a re-infection some time during late childhood or early adolescent life. It must be pointed out, however, that the lesions so produced often remain latent, and clinically manifest tuberculosis may not develop for months or years after re-infection.

Endogenous and Exogenous Infection.

The long period during which it was taught that practically everyone reaching adult life had already been infected with the tubercle bacillus was characterized also by the belief that pulmonary tuberculosis of the adult type was the result either of activation of an old pulmonary lesion or of endogenous superinfection. It is now realized that, except in crowded urban communities, a proportion of persons may reach adult life without becoming infected, and more attention is therefore being devoted to the part played by exogenous infection in the pathogenesis of pulmonary tuberculosis. It is known that adults who become infected for the first time may develop a form of pulmonary tuberculosis indistinguishable from that occurring in those with a recognizable healed primary lesion, suggesting that, though the peculiar nature and course of adult pulmonary tuberculosis may be determined to some extent by experience of a previous infection, the natural resistance of the primarily infected healthy adult may alone suffice to bring about the same result.

The main problem concerns the genesis of pulmonary tuberculosis in those who have already been infected during childhood. Is the disease due to endogenous or exogenous superinfection? As invariably happens when the data are insufficient, there is a sharp cleavage of opinion on this point. Since Opie's work, however, the protagonists of the exogenous view have been gaining ground. We have no space here to discuss the evidence in detail; reference to one or two representative papers must suffice.

There is a wealth of evidence to show that pulmonary tuberculosis is much commoner among family contacts than among non-contacts (see p. 1302). Moreover Lloyd and Macpherson (1936) found that about 4 out of every 5 young adults suffering from pulmonary tuberculosis who had been in contact with a known case of infection developed the disease within five years of the last known exposure—a time relationship that is difficult to understand if the disease was of endogenous origin. Observations by Plunkett, Weber, Siegal and Donk (1940) in the Newark State School for Mental Defectives showed that during a period of three years 13 new cases of pulmonary tuberculosis developed among tuberculin-positive patients. Every one of these had been in close contact with an infectious case. Among those who had not been exposed to known infection, not a single case was reported. Israel and DeLien (1942), who studied the fate of 932 persons of 14 years or over who had had a positive tuberculin reaction during childhood, found that in white persons the mean annual morbidity rate among those exposed to household infection after 14 years of age was 2 per cent., as against only 0·1 per cent. in those with no household exposure. The morbidity rate, however, in those with radiographical evidence of a primary tuberculous lesion was, in the absence of household exposure, not significantly higher than in those without such a lesion. The authors conclude therefore that pulmonary tuberculosis in adolescence and early adult life is more often the result of household exposure after childhood than before, indicating that in early adult life exogenous infection is more important than the endogenous reactivation of lesions acquired in early childhood.

Whether exogenous superinfection gives rise to pulmonary disease directly, or whether, as Wingfield (1942) suggests, it brings about an endogenous exacerbation by causing a focal tuberculin reaction, will be impossible to decide till we know a great deal more about the part played by allergy in the mechanism of immunity to tuberculosis (see pp. 1330–1336).

If it is true that exogenous infection in adult life may result in pulmonary tuberculosis, then far more care should be exercised than has hitherto been general

in protecting not only children but adults, even tuberculous adults, against the risk of exposure to infection. There is still a widespread tendency to neglect or minimize the risk of adult infection. In the absence of strong evidence to the contrary, we consider this attitude to be dangerous and reprehensible. Experience of the control of infectious disease, whether of bacterial or virus origin, has established the principle that avoidance of infection constitutes the first line of defence. Vaccination by natural or artificial means plays, as a rule, a much less important rôle. We see no reason why tuberculosis should be regarded as different in this respect from other diseases.

TUBERCULOSIS OF BOVINE ORIGIN. FREQUENCY AND MODE OF INFECTION

Frequency.—The frequency of this type of tuberculosis varies greatly in different countries and in different parts of the same country, depending in general on the incidence of tuberculosis in cattle and the quantity of raw milk consumed. In Scotland the percentage of bovine infection in all forms of tuberculosis is higher than in England. Taking Great Britain as a whole, there were in 1931 about 2,600 deaths and 6,250 notifications (Report 1934). Of the deaths, about three-quarters occurred in children under 15 years of age. These figures are calculated on the proportion of bovine infections in different forms of tuberculosis, and are subject to the error of random sampling. Making allowance, however, for such an error, and for the fact that the notifications probably underestimate the true number of cases, it is clear that the bovine tubercle bacillus is responsible in Great Britain for a large number of deaths and for an immense amount of suffering, invalidity, and often permanent deformity.

In England and Wales about 6·0 per cent. of all deaths from tuberculosis are due to infection of bovine origin. The frequency in other countries is less certain. In the United States, Park and Krumwiede (1910), who examined 436 strains of tubercle bacilli, of which 291 were derived from patients with pulmonary tuberculosis, found that 7·57 per cent. were of the bovine type. This percentage, however, is not applicable to the present frequency of tuberculosis of bovine origin. Since 1917 an intensive campaign has been carried out under the Federal Government to eradicate tuberculosis in cattle, and the extent to which these animals are infected is now on an average probably only about one per cent. of that in Great Britain. Clinical observers are unanimous in agreeing on the comparative infrequency in the United States of cervical and mesenteric glandular tuberculosis in young children, both of which manifestations in this country are generally due to the bovine bacillus (see Reichle 1936). In Germany, Austria, Denmark, Sweden, Poland, and the Netherlands the disease appears to be fairly frequent, though perhaps less so than in Great Britain (see Klimmer 1931, Lange 1932, 1937, Blacklock 1932, Tobiesen *et al.* 1935*a*, *b*, de Lange and de Bruin 1935, Piasecka-Zeyland 1937, Ruys 1937, van der Hoeden 1937, van der Hoeden and Pannevis 1937, Hedvall 1942.)

Source of Infection.—Cattle form the great reservoir of infection with the bovine bacillus. In this country about 40 per cent. of all milch cows react to the tuberculin test; about 40 per cent. slaughtered in public abattoirs show naked-eye lesions of tuberculosis; and about 0·5 per cent. are actually excreting tubercle bacilli in their milk (Report 1932*a*, 1934, Savage 1933). The proportion of milk samples containing virulent tubercle bacilli varies with the nature of the sample and the part of the

country from which it is derived. On an average about 7 per cent. of samples of mixed milk from individual farms contain tubercle bacilli, the proportion varying from about 2 per cent. in Somerset to about 21 per cent. in Cheshire (Report 1932*a*, Gloyne 1932, Pullinger 1934, 1935, Parry and Hall 1935). In Scotland the proportion seems to be even higher (Report 1933*a*).

We have no space to furnish the complete evidence incriminating milk as the main cause in man of tuberculosis of bovine origin. The general nature of the evidence rests on (1) the parallelism in different countries between the frequency of tuberculosis in cattle and of tuberculosis of bovine origin in man ; (2) the high proportion of alimentary infections in man due to the bovine type ; (3) the frequency of non-pulmonary tuberculosis of bovine origin in infancy and childhood ; (4) the comparative infrequency of tuberculosis of bovine origin in areas in which the majority of the milk, even though heavily infected, is pasteurized or boiled before use ; (5) the production of tuberculosis in animals fed on infected milk (Griffith 1907, Wilkie *et al.* 1937). The most convincing evidence is afforded by the observations of Price (1932, 1934) in Toronto on the frequency of the bovine type of bacillus in non-pulmonary tuberculosis of childhood. Of 300 tuberculous children examined under 14 years of age, 15 per cent. were found to be infected with the bovine type. Without exception, these children came from parts of Ontario outside Toronto where pasteurization of milk was not carried out, and all had a history of being fed for some time on raw milk. In Toronto, where pasteurization has been compulsory since 1915, not a single case of tuberculosis of bovine origin was found, in spite of the fact that 26 per cent. of pooled samples of raw milk coming into the town contained tubercle bacilli.

The bacilli in the milk may pass through the lymphoid tissue of the mouth and nasopharynx, and reach the cervical glands, where they give rise to disease. The tonsil seems to be not uncommonly infected (Saenz *et al.* 1933). Alternatively they may pass through the intestinal mucosa and invade the mesenteric group of glands. There seems to be little doubt that the organisms may traverse the mucous membrane without giving rise to any lesions in the mucosa itself. Once they have gained access to the lymphatic system, they may be distributed in the body either by direct spread, by the lymph stream, or by the blood stream. Blood-borne infection appears to be mainly responsible for miliary tuberculosis, meningitis, bone and joint disease, and genito-urinary tuberculosis.

Pulmonary tuberculosis of bovine origin is mainly a rural disease. On this point both British and continental workers are in agreement (Lange 1937, Griffith 1937*a*, 1938, 1941, Ruys 1937, van der Hoeden 1937, Griffith and Smith 1940, Hedvall 1942, Cutbill and Lynn 1944). The mode of infection, however, is still open to dispute. Most of the work in this country suggests that the disease follows most commonly on glandular tuberculosis acquired through alimentary infection, but in Germany Lange (1931, 1932) has brought evidence to show that in farm workers infection may result from the inhalation of tubercle bacilli expectorated by tuberculous cattle (see also Hedvall 1942). In cases following on primary glandular infection the incubation period ranges from less than a year to 26 years or more (Griffith 1938). Griffith (1937*a*) regarded the disease as the final phase of an infection acquired in childhood, adolescence, or even adult life through the consumption of tuberculous milk. Occasionally infection is transmitted from one person to another by contact (Griffith 1938). The clinical course of the disease is often rapid and a considerable proportion of cases prove fatal.

Summarizing, we may say that practically all non-pulmonary, and a variable proportion of pulmonary, cases of bovine origin are contracted through the agency of raw milk or cream. *Cheese* and *butter*, it may be noted, probably play an insignificant part in the transmission of infection in Great Britain. Over 80 per cent. of butter is imported and practically all imported butter is made from pasteurized cream. In cheese the tubercle bacillus dies out fairly quickly, and is usually dead before the ripening process is complete. Only in farm butter and in soft cheese, *i.e.*, unripened cheese eaten within a few days of its preparation, are tubercle bacilli likely to be found alive.

It is of interest to recall the changes that our views on this type of tuberculosis have undergone in the present century. At the London Congress on Tuberculosis in 1901, Koch asserted, on the basis of quite inadequate experimentation, that bovine bacilli were virtually non-pathogenic to human beings. His views were attacked by McFadyean (1901) and by Ravenel (1901) on the basis of strong, though circumstantial, evidence. As the result of considerable opposition, Koch modified his views at the Washington Congress in 1908, to the extent of admitting that human beings might be infected with bovine tubercle bacilli, though he maintained that serious disease due to these organisms was very rare, and that preventive measures to protect the human population against tuberculosis of bovine origin were quite unnecessary. The extensive labours of the Royal Commission on Tuberculosis in this country, and of continental and American workers, revealed the fallacy of Koch's teaching, and showed that non-pulmonary tuberculosis in childhood was frequently caused by the bovine bacillus. The more recent work of Griffith, Munro, Lange, and others has now drawn attention to the occurrence of bovine bacilli in pulmonary tuberculosis; and infections of bovine origin as a whole must be regarded as a serious menace to the human population in those countries where tuberculosis of cattle is common. The evidence suggests that the bovine bacillus is quite as virulent for man as the human bacillus, and possibly even more so (see Griffith 1925*b*). The result of Koch's teaching was of more than academic importance. By exonerating cows from all blame in the causation of tuberculosis in man, it put back the clock of veterinary preventive medicine to a degree far greater than is generally appreciated. It further removed the rationale for boiling milk, which had hitherto been accepted on empirical grounds, and delayed for a long time the adoption of pasteurization. Even now we are not free from its trammels, and the public health expert has to fight a continuous battle against the ignorance and prejudice resulting from an authoritative statement made on inadequate evidence 45 years ago. (For general review of tuberculosis of bovine origin, besides those already quoted, see Griffith 1927, 1932*c*, 1937*a*, 1938, 1941, Report 1931*b*, Gervois 1937, Myers 1940, Wilson 1942.)

DIAGNOSIS

Microscopical Examination in Diagnosis.—Tuberculosis is one of the few diseases in which a diagnosis can often be made by microscopical examination alone. The simplest method is to stain a film of sputum, pus, or other pathological product with Ziehl-Neelsen's stain, using 25 per cent. sulphuric acid for decolorization, and 1 per cent. aqueous methylene blue for counterstaining. Numerous other methods of staining, however, have been recommended from time to time, such as Spengler's

(1907), Herman's (1908), Mori's (1911), Bozzelli's (1914), Schulte-Tigges' (1920), and Pottenger's (1942). When very few organisms are present, attempts to increase their numbers or to render their distribution in the film more uniform may be made by (*a*) chemical concentration methods, such as the antiformin method or the methods described by Faisca (1921), Grysez and Bernard (1920), G. Mayer (1926), and S. R. Douglas and Meanwell (1925); (*b*) chemical flocculation methods, such as that of Hanks, Clark and Feldman (1938); (*c*) flotation methods, such as those described by Andrus and MacMahon (1924), Pottenger (1931), Edwards, Lynn and Cutbill (1936), C. R. Smith (1938), and Hanks and Feldman (1940).

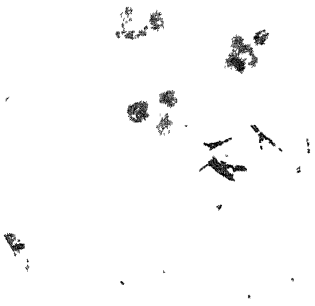

FIG. 279.—*Mycobacterium tuberculosis*, in urine, showing the characteristic clumps (× 1000).

Urine should be centrifuged, and films made from the deposit (Fig. 279). When examining the cerebrospinal fluid, it is best to allow the fluid to stand till a fibrinous clot forms; this should be removed with a platinum loop, spread on a slide, and stained in the usual manner for acid-fast bacilli. Otherwise it should be centrifuged and treated like urine.

In both pulmonary and non-pulmonary tuberculosis the bacilli may often be found in the fæces (Alexander 1910, Costa 1926, Sergent 1926, Sykes 1926, Verdina 1926); for their detection some concentration method, such as the ligroin method, should be employed. Examination of the fæces is chiefly of use in children, who generally swallow their sputum, and in cases of closed pulmonary tuberculosis in which there is no sputum. It has been suggested that the bacilli may be excreted from the blood into the bile, and thus reach the fæces (Alexander 1910, Calmette 1920, Remlinger 1923, Koizumi 1924, Verdina 1926).

Examination of the fasting stomach contents obtained by gastric lavage is used extensively in the diagnosis of pulmonary disease in children, and in adults with little or no sputum (Kereszturi *et al.* 1932, 1933, Collis and Brockington 1933, Poulsen and Andersen 1934, Gourley 1934, Nalbant 1934, Stadnichenko, Cohen and Sweany 1940, Webster 1941, 1943, Davies and Doherty 1942, Robinson and Dunn 1943). The method was described originally by Meunier in 1898, but was not adopted as a routine till it was rediscovered by Armand-Delille (1927) nearly 30 years later. To avoid the mild unpleasantness of the passage of a stomach, or preferably nasal, tube, simpler methods of obtaining sputum have been described by Behmann (1930) and Wood (1936), in which the patient is made to cough by the insertion of a swab or laryngeal mirror into the throat. The material so obtained can be swabbed over a slide and stained in the usual way, or better inoculated on to suitable culture media. It is doubtful, however, whether this method is as satisfactory as that of examining the stomach contents. According to Mishulow and her colleagues (1934), repeated examination of fæces is probably as satisfactory as that of gastric lavage specimens.

In pus the bacilli are often very difficult to demonstrate; Gardner (1926), following Spengler (1907), recommends the use of half-saturated aqueous picric acid as a counterstain.

The microscopical method of examination, though very simple, must not be undertaken without due regard to the errors of the technique employed. Microscopical examination alone cannot distinguish between tubercle bacilli and other types of acid-fast bacilli. Besides saprophytic acid-fast bacilli of the *Mycobacterium* group, which are widespread in hay, straw, dust, animal litter, soil, and water, there are a number of other organisms, such as the leprosy bacillus, Johne's bacillus, and some species of *Actinomyces*, which are acid-fast and which may occasionally give rise to confusion.

In order to avoid contamination of the material with these organisms, strict attention must be paid to the preparation of the actual films. In particular, all stains and reagents should be made up with fresh glass-distilled water; and all glass-ware should be soaked in 50 per cent. nitric acid for at least 15 minutes. Only new slides should be employed, since there is no simple method of removing acid-fast bacilli from slides on to which they have been fixed and stained, and every slide should be thoroughly flamed in a Bunsen burner immediately before use. If the material has to be rubbed up in a drop of water on the slide fresh glass-distilled water or water from a hot tap in constant use should be used, since acid-fast bacilli are usually abundant in cold-water taps (see Chapter 16). Care must be taken to avoid contamination of the cedar-wood oil reservoir from the surface of a previous film, and the oil-immersion objective should always be cleaned after examining a positive film. All apparatus, particularly if made of metal or rubber, used in the collection of catheter and other specimens, should be kept under conditions that will prevent the growth of saprophytic acid-fast bacilli on their surface (see A. H. Wells 1936).

When all these precautions have been taken, the importance to be attached to the finding of acid-fast bacilli will vary with the nature of the material examined. While acid-fast bacilli in sputum or cerebrospinal fluid may be regarded as almost certainly diagnostic of tuberculosis, their presence in fæces or urine must be interpreted with far greater caution, since the presence of saprophytic acid-fast, including smegma, bacilli cannot with certainty be excluded. In blood so many artefacts are liable to be present that it is extremely doubtful whether the search for acid-fast bacilli is justified at all.

Of recent years *fluorescence microscopy* has been used for the examination of tubercle bacilli. The method depends on the observation that tubercle bacilli, stained with a suitable dye and irradiated with ultra-violet light, transform the invisible short waves to longer visible rays. Hagemann (1937*a*, *b*), who introduced the method, at first advocated berberine sulphate as the dye, but later he (1938) recommended auramine. Observed through a yellow filter in the eyepiece, the fluorescent organisms appear as golden yellow rods against a violet background. The use of a dry 4 mm. objective with a × 10 eyepiece enables a wider field to be covered than with a 2 mm. oil-immersion lens. Numerous favourable reports have been published on the method (for references see Richards, Kline and Leach 1941, Bogen 1941, Lempert 1944), demonstrating its superiority over the Ziehl-Neelsen stain. It seems clear, however, that not all tubercle bacilli in a preparation are revealed by fluorescence microscopy, and that a higher proportion of positive results is obtained by cultural methods.

Cultural Methods in Diagnosis.—Increasing use is now being made of cultural methods in the diagnosis of tuberculosis. Uncontaminated material should be seeded directly on to a suitable medium. Contaminated material, such as sputum or gastric contents, should be first treated for 10–30 minutes with 15 per cent. antiformin, 10 per cent. HCl, 4 per cent. NaOH, or for 30–60 minutes with 5 per cent. oxalic acid, or some other agent capable of killing off non-acid-fast organ-

isms. Many different media have been recommended, particularly by American workers.

A. S. Griffith and F. Griffith (1907), working for the Royal Commission on Tuberculosis many years ago, made a careful comparison of whole egg, egg yolk, egg yolk agar, and various serum media, and found that the most satisfactory medium for *primary* cultivation was Dorset egg (3 parts egg to 1 part saline, sloped and inspissated at 75° C. for 2 hours on 2 successive days). Our own experience bears this out. Dorset's egg medium, which was prepared independently by A. S. Griffith and F. Griffith (1907), or a medium made up with 2–3 parts of egg yolk to 1 part of tap water (Corper and Cohn 1933*b*, 1942, Schwabacher 1937, McCarter and Kanne 1942), has proved superior to all the other media—Petroff, Petragnani, Löwenstein, Herrold, Corper and Uyei, Woolsey—commonly recommended. Many of these more complex media contain dyes, which have some inhibitory action on the growth of the organisms, and many contain glycerol, which has a selective action favouring the growth of the human tubercle bacillus at the expense of the bovine. The plain Dorset or egg yolk medium is free from these defects, and is equally suitable for the growth of both human and bovine types (see also Griffith, A. S., 1935).

Great care must be used to avoid contamination of the material with saprophytic acid-fast bacilli. Glass-stoppered vessels sterilized in the dry oven or the autoclave should be used. Rubber corks, and certainly bark corks, are to be avoided, since they may contain acid-fast bacilli. Even using the greatest precautions, it is impossible to avoid occasional contamination of the material with saprophytic acid-fast bacilli, and numerous workers have recorded the development of these organisms in otherwise sterile cultures (see Tiedemann 1931, Beaven and Bayne-Jones 1931, Pinner 1932, Cummins and Williams 1933, Griffith 1933, Bruynoghe and Adant 1933, Pinner 1935, Lester 1938). The fact that they usually are contaminants, and are not derived from the tissues, is evident from the fact that Schwabacher (1933) obtained them in cultures from normal rabbit blood.

Under favourable conditions the cultural method is more delicate than the microscopic method for the demonstration of acid-fast bacilli. Corper and Cohn (1933*a*) estimate that for the rapid microscopic detection of these bacilli in sputum, there must be about 100,000 per ml., whereas for their detection by the cultural method 10–100 organisms per ml. suffice. Some workers regard the cultural as more delicate even than the animal inoculation method (see Norton *et al.* 1932). The great drawback to the cultural method is that it provides no proof that the acid-fast bacilli which have been cultivated are really tubercle bacilli or are derived from the material under examination. No organism should, in fact, ever be reported as a tubercle bacillus until it has been finally identified by animal inoculation.

Of recent years, mainly owing to the assertion of Löwenstein that tubercle bacilli can be isolated from the blood of a high proportion of patients suffering not only from pulmonary and non-pulmonary tuberculosis, but also from such diseases as articular rheumatism, polyarthritis, chorea, multiple sclerosis, schizophrenia, and retro-bulbar neuritis, great attention has been paid to the subject of *tuberculous bacillæmia*. We do not propose to discuss this work in detail. Though tubercle bacilli may be demonstrated by cultural and animal inoculation methods in as many as 5–10 per cent. of severe, advanced and progressive cases of pulmonary tuberculosis, in 30–40 per cent. of cases of miliary and meningeal tuberculosis, and in 50 per cent. of fatal tuberculous cases examined post mortem, they can very rarely be found in the early stages of pulmonary or non-pulmonary tuberculosis. A search for these organisms in the blood is therefore of little value in diagnosis. The great majority of workers have entirely failed to substantiate Löwenstein's findings, which were almost certainly due to gross errors in technique. The whole subject has been critically reviewed by G. S. Wilson (1933). See also Report (1935*c*).

Serological Methods in Diagnosis.—Serological methods of diagnosis are not, on the whole, satisfactory.

Arloing and Courmont (for references see Wilson, G. S., 1925) in 1898 recommended the *agglutination test.* They obtained a homogeneous suspension of tubercle bacilli by growth of a special strain—now known to be of avian type (Wilson, G. S., 1925)—in glycerine broth. The reaction was considered positive when the organisms were agglutinated by the patient's or animal's serum in a dilution of 1–5 to 1–20. Positive results were obtained in 95 per cent. of early cases of pulmonary tuberculosis and in 50 per cent. of cases of surgical tuberculosis. The percentage, however, of normal persons and of patients suffering from non-tuberculous diseases who reacted positively was as high as 30–67 per cent. Numerous other workers (Mongour and Buard 1898, 1899, Beck and Rabinovitsch 1900, 1901, Bendix 1900, Neisser 1900, Koch 1901, Chang 1922, Courmont and Papacostas 1923, Spehl 1923, Karmann 1924) have reported on this test, and the general consensus of opinion is that as a method of diagnosis it is unreliable; many patients with tuberculosis fail to react, and many persons who appear perfectly well do react.

The *complement-fixation reaction* stands on a slightly firmer basis, though its value is still very much disputed. Numerous methods of performing the test have been devised, and still more numerous antigens. The French generally employ Calmette and Massol's technique with Besredka's antigen. Table 104, taken from Rieux (1926), gives some of the results that have been obtained.

TABLE 104

COMPLEMENT FIXATION IN TUBERCULOSIS.

Type of Disease.	Positive Results.
Pulmonary tuberculosis with positive sputum	85%
Clinically tuberculous pleurisy	46·6%
Tuberculous peritonitis	80%
Tuberculous meningitis	Rarely positive
Glandular tuberculosis	38%
Bone and joint tuberculosis	50%
Renal tuberculosis	90%
Healthy persons	10–15%
Persons suffering from non-tuberculous diseases	10%

Rieux concludes that every patient giving a strongly positive reaction, and who is not suffering from syphilis, leprosy, or malaria, is tuberculous. Besredka and Manoukhine (1914) conclude that in the first stage of tuberculosis the reaction is always positive; in the second stage it is generally positive; in the third stage it is often weakly positive or negative—especially before death. In this country the reaction is not held in such favour. Coulthard (1923) obtained the highest percentage of positive reactions in chronic pulmonary tuberculosis; he regards a strongly positive reaction as indicative of a relatively high degree of immunity, irrespective of the extent of the disease. In acute forms of tuberculosis, such as the miliary and acute pneumonic forms, and in tuberculous meningitis, the reaction was generally negative. In early pulmonary tuberculosis and in actively progressive pulmonary tuberculosis the results were disappointing. Sellers and Ramsbottom (1922) concluded that the test was of little value in diagnosis.

That the test is generally positive in chronic pulmonary tuberculosis there is little doubt; but these cases can generally be diagnosed by other means. In the early stages of the disease, when diagnosis by the usual methods is in doubt, the complement-fixation reaction is unreliable. It can at best be used only as a sub-

sidiary method, and even as such it must be interpreted with great reserve. (For further literature on the test, see Calmette and Massol 1914, Dudgeon, Meek and Weir 1914, Meek 1914, Radcliffe 1915, Urbain and Fried 1921, Brocq-Rousseu, Urbain and Cauchemez 1923, von Gutfeld and Weigert 1924, Douglas, S. R., and Meanwell 1925, Salomon and Valtis 1925, Valtis 1925, Wadsworth *et al.* 1930, Hünigen 1932, Rice *et al.* 1933, Urgoiti and Beato 1934, Hassegawa and Kochi 1939.)

The *precipitin reaction*, obtained by mixing the patient's serum with tuberculin, is of little or no practical importance. It is of interest to note that the antigen responsible for the complement-fixation and the precipitin reactions is a non-protein gum (Laidlaw and Dudley 1925, Mueller 1926).

Allergic Reactions in Diagnosis.—The tuberculin reaction may be performed in various ways; the tuberculin may be (1) rubbed on to the scarified skin—cutaneous reaction of von Pirquet (1907); (2) incorporated in an ointment and rubbed into the skin—percutaneous reaction of Moro; (3) injected intracutaneously—Mantoux's reaction (1910); (4) dropped into the conjunctiva—Calmette's ophthalmic reaction; (5) injected subcutaneously—Koch's original method (1890) (see p. 1328); (6) applied to the skin on a piece of thin filter paper impregnated with undiluted tuberculin and then dried—the patch test of Vollmer and Goldberger (1937, 1938, 1939*a*, *b*). Both the von Pirquet and the graded intradermal tests have already been described (pp. 1300–01). There is no question that the latter method is to be preferred. Nearly all persons with either a latent or an active tuberculous infection react positively to tuberculin, except when suffering from advanced disease, severe cachexia, or one of the infectious exanthemata. A positive reaction indicates the presence of a tuberculous focus in the body, but does not distinguish between an active and an inactive lesion. Except in the first few years of life a positive reaction is of very limited value in the diagnosis of clinical tuberculosis. On the other hand, a negative intracutaneous reaction, particularly to a 1/100 or 1/10 dilution, practically excludes the existence of tuberculous infection at any age (see Hart 1932). The Vollmer patch test has found some favour for use in infants and young children, but it is clearly neither as reliable nor as sensitive as the graded intradermal test (Report 1939, Kereszturi 1941).

The interpretation of different degrees of reactivity to tuberculin in terms of either diagnosis or prognosis (see von Gröer 1932, Johnston *et al.* 1934, Daniels 1944) is still open to doubt. As a rule children having a history of contact with tuberculosis, and patients suffering from active tuberculosis, have a very high sensitivity to tuberculin (Furcolow *et al.* 1941). For example, of 468 tuberculous patients investigated by Furcolow, Hewell and Nelson (1942), 99·6 per cent. reacted to 0·0001 mgm. or less of a particular batch of P.P.D., and some reacted even to 0·000000001 mgm. On the other hand, it was found that patients who were seriously ill, who had a short history or the pneumonic form of disease, and who were apparently resisting badly, had a lower degree of sensitivity.

It may be noted that in childhood a positive reaction may become negative with complete healing of the lesion, though the frequency with which this occurs is not known (see Lloyd and Macpherson 1933, Opie 1935, Zacks and Sartwell 1942). Dahlstrom's (1940) conclusion, however, that a high proportion of weak reactors in children become negative with the passage of years is very questionable; it has been criticized on the ground that the dilution of tuberculin he used was so low that many of the reactions he obtained were probably non-specific

(Furcolow *et al.* 1941). The allergic condition is often maintained by the persistence of tubercle bacilli in quiescent or healed lesions. According to Opie and Aronson (1927) tubercle bacilli are frequently detectable by guinea-pig inoculation even in apparently normal lung tissue, though Feldman and Baggenstoss (1938, 1939) and Saenz and Canetti (1938) doubt this. Howe (1938) has recorded rapid variations in the sensitivity of both tuberculous and non-tuberculous persons to tuberculins, associated to some extent with changes in blood pressure. It is generally assumed that a positive tuberculin reaction precedes or accompanies the appearance of recognizable lesions by X-ray examination, but Levine (1939) has brought evidence to show that in infants under one year of age the reverse sequence may be noted. This may perhaps be due to the poorer antibody response in early infancy than in later years. The comparative liability of tuberculin-positive and tuberculin-negative reactors to develop pulmonary tuberculosis will be considered later (pp. 1330–33).

A *delayed tuberculin reaction* has been described by Daniels (1943), developing several weeks or months after the intradermal injection of old tuberculin. It is regarded as an indication that the person has become infected with tuberculosis some time after the test. The reaction is apparently due to the persistence of tuberculin in the skin. If this interpretation is correct, the delayed reaction may serve as a useful indicator of primary infection.

Animal Inoculation Tests in Diagnosis.—The most delicate test for tubercle bacilli is animal injection, and the most suitable animal is the guinea-pig. The susceptibility of the guinea-pig is extremely high ; even minute amounts of infective material will render this animal tuberculous. The material—sputum, pus, milk, etc.—should be injected subcutaneously or intramuscularly into the thigh ; the advantage of intramuscular injection is that the local abscess which forms does not ulcerate through the skin. It is wise to inject at least two animals, in case one dies of secondary infection—an occurrence which is very common after the inoculation of urine or fæces. One animal should be killed 3–4 weeks later, and if no signs of tuberculosis are apparent, the other should be kept for 6–8 weeks after inoculation before being killed.

In positive cases killed at 6–8 weeks there will be found (1) a caseous local lesion ; (2) enlargement and caseation of the femoral, inguinal, sublumbar, portal, mediastinal, and cervical glands, the severity of the lesions diminishing as the distance from the site of inoculation increases ; (3) enlargement of the spleen with the presence of irregular necrotic areas ; (4) yellowish-green necrotic areas in the liver ; (5) a few discrete spherical tubercles in the lungs (for further details see p. 425). In animals killed after 3 or 4 weeks the lesions are less severe, and are restricted mainly to the lower portion of the chain of glands and to the spleen and liver. However experienced the worker may be, it is of paramount importance to make a microscopical examination for the presence of acid-fast bacilli. Direct smear preparations should be made from two or three enlarged lymphatic glands, as well as from the spleen, liver, and lungs, and a diagnosis of tuberculosis should not be made unless acid-fast bacilli are found in the internal organs or in glands not directly draining the site of inoculation. The reason for this is that saprophytic acid-fast bacilli may be present in the local lesion and the regional lymphatic glands, though they are usually incapable of penetrating further into the tissues after inoculation by the intramuscular route. It is dangerous to make a diagnosis of tuberculosis unless at least one gland shows caseation. In all doubtful cases cultures should be put up on ordinary media for the diagnosis of *Salmonella*, *Brucella*, *Pasteurella*, and pyogenic infections, and on to suitable media for the growth of tubercle and saprophytic acid-fast bacilli. Whenever necessary, a fresh animal should be inoculated intramuscularly with some ground-up pathological

material, and with any acid-fast bacillus that may develop in culture. Special care must be taken in the microscopic examination of material to guard against the presence of acid-fast bacilli derived from water or from tuberculous tissue on the instruments used for making a post-mortem examination, since boiling does not destroy their property of acid-fastness. Heating the instruments in a Bunsen flame to dull redness usually suffices for this purpose.

The tuberculin test, made by inoculating 0·1 ml. of a 1/50 to 1/100 dilution of old tuberculin into the skin of the flank, may be used for the diagnosis of tuberculosis in a guinea-pig during life (see p. 1328). It is of particular value in furnishing a guide to the time at which the animal should be killed. The test is usually very reliable, provided no reaction is considered positive unless the local lesion reaches 10 mm. in diameter. Tuberculosis, however, should never be diagnosed on a tuberculin test alone; the result must always be confirmed by post-mortem examination.

IMMUNITY IN TUBERCULOSIS

Our knowledge of the defensive mechanism of the animal body against the tubercle bacillus is very incomplete. A study of the humoral antibodies—notably agglutinins, complement-fixing bodies, and opsonins—has failed to throw much light on the subject; there is apparently no strict relationship between the antibody content of the person's serum and his resistance to tuberculosis. Most of the knowledge that we have gained consists of isolated observations, which it is impossible as yet to piece together except in the form of a purely tentative hypothesis. A summary of these observations must necessarily be disjointed.

Koch's Phenomenon.—If a healthy guinea-pig is injected subcutaneously with a pure culture of tubercle bacilli, the slight local lesion caused by the injection heals in a few days; in 10 to 14 days, however, a hard nodule appears, which breaks down and remains as an ulcerating sore till the animal dies; the regional lymphatic glands swell considerably and undergo caseation. But if a tuberculous guinea-pig—one that has been injected 4 to 6 weeks previously—is injected subcutaneously into the opposite thigh with a pure culture of tubercle bacilli, the slight local lesion heals rapidly, but no nodule forms. Instead, on the 1st or 2nd day after inoculation, a circular dark-coloured area of induration, about ½ to 1 cm. in diameter, appears at the site of injection. The next day the skin over this ecchymotic area undergoes necrosis; and later it is thrown off leaving a shallow ulcer, which heals quickly; the focal lymphatic glands remain unaffected. This reaction was first observed by Koch (1891*a*), and is known as Koch's phenomenon. For its success three conditions are necessary (von Löwenstein 1913): (1) the primary infection must be a slight one, so that the disease runs a chronic course; (2) the re-infecting dose must be given as late as possible after the sensitizing dose; the longer the animal has been infected the higher is its resistance; (3) the re-infecting dose must not be too large.

It is clear that the reaction of a tuberculous guinea-pig to a fresh infection is different from that of a normal guinea-pig to a primary infection. Some experiments conducted by Debré and Bonnet (1922) will make this clearer.

A. One group of guinea-pigs was injected with 0·1 mgm. of tubercle bacilli every day for 5 days. *Result.*—Five nodules appeared, identical in their period of incubation (8 to 10 days), in their evolution, and in their accompanying glandular reaction. *B*. Another group of guinea-pigs was injected with 0·1 mgm. of tubercle bacilli every 5 days on five

successive occasions. *Result.*—The first two nodules and their accompanying glandular reaction were identical with those in Series *A*. The third nodule appeared after a shorter incubation period than the first two, was much smaller—the size of a lentil instead of a nut—did not ulcerate, and caused only a slight glandular swelling. The fourth and fifth nodules were identical with the third. *C*. Another group of guinea-pigs was injected with 0·1 mgm. of tubercle bacilli every 10 days on five successive occasions. *Result.*—The first nodule and its accompanying glandular reaction were similar to those in Series *A*. The second and third nodules resembled the 3rd, 4th, and 5th nodules of Series *B*. The fourth nodule produced either a typical Koch's phenomenon, or rapid abscess formation followed by cicatrization, without any glandular enlargement. The fifth nodule constantly provoked the typical eschar described by Koch. With these particular doses, it will be seen that Koch's phenomenon did not appear till about 6 weeks after the first injection. The main lesson to be learnt from this experiment is that the "chronical" supersensitization of a tuberculous guinea-pig is impracticable after the appearance of the local abscess. Before the local lesion has appeared the animal reacts to a fresh infection just as a normal animal; but once the local lesion due to the first injection has developed—generally in 8 to 10 days—the lesions produced by subsequent injections become less and less, till after 6 weeks the freshly injected organisms call forth an acute reaction, quite unlike the chronic process that follows a primary infection.

These observations are similar to those made on experimental syphilis, which have shown that it is possible to produce in the ape a series of chancres, so long as the second injections are made before the appearance of the primary chancre; once the primary chancre has appeared, further inoculation of syphilitic material fails to produce a fresh chancre. The guinea-pig that has developed a local tuberculous lesion, or the ape that has developed a primary chancre, reacts differently from a normal animal to a fresh infection. It is, so to speak, at once more sensitive and more resistant to the infective material than the normal animal. This state of hypersensitiveness is generally known as *allergy*. Whether the immunity is only a symptom-immunity, or whether it is sufficiently high to prevent the actual invasion of the organisms at the site of the second injection is not known, but the experiments of Thomsen and Pedersen-Bjergaard (1933) suggest that it may be of the latter type.

Koch (1891*a*) found that his phenomenon could be reproduced even when dead tubercle bacilli were employed for the second injection. Killed suspensions of tubercle bacilli, when injected subcutaneously into normal guinea-pigs, give rise merely to a local sterile abscess; there is no constitutional disturbance whatever. But if they are injected into a tuberculous guinea-pig, one of two things happens, depending on the dose: if a large dose is used the guinea-pig dies in 6 to 48 hours; if a smaller dose is used, there is a local necrosis of the skin—Koch's phenomenon. The allergic guinea-pig, in fact, responds to the injection of dead tubercle bacilli in very much the same way as to that of living bacilli. Koch therefore argued that the reaction must in each case be due to some chemical substance present alike in living and dead bacilli. This active principle he endeavoured to obtain in a soluble form (Koch 1891*b*).

Tuberculin : Preparation, Purification, and Standardization.—Koch grew tubercle bacilli for 6 to 8 weeks at 38° C. in flat-bottomed flasks containing 5 per cent. glycerine broth. The culture was then placed in a water-bath at 100° C., evaporated to 1/10 of its volume, and freed from bacilli by filtration through a clay or kieselguhr candle. The resulting filtrate was a clear, brown, syrupy fluid; as it contained

40–50 per cent. of glycerine, no antiseptic was required for its preservation. It is generally known as Koch's *old* or *original tuberculin*, and contains all the substances in the culture medium, including those formed from the medium by the bacilli, and the disintegration products of the bacilli themselves, not precipitated by 50 per cent. glycerine. This old tuberculin was found to contain in an impure form the toxic constituents that Koch had been looking for. It is heat-stable, and, when undiluted, will resist autoclaving for half an hour.

Later, owing to the failure of old tuberculin in the treatment of tuberculosis, Koch (1897) prepared a series of tuberculins in the hope of obtaining one that should be immunizing without being toxic. These, which were called Tuberculin A, Tuberculin O, Tuberculin R, and Tuberculin BE, are now mainly of historic interest (for their preparation see Topley and Wilson, 2nd edition, p. 1041).

Of late years attention has centred on the preparation of a product as free as possible from substances capable of giving rise to non-specific reactions when used for graded intradermal tuberculin tests. For this purpose synthetic media have replaced broth (Long and Seibert 1926, Douglas and Hartley 1934*b*). From the old tuberculin thus produced a substance known as *purified protein derivative* (P.P.D.), containing the active principle of tuberculin, has been isolated and purified by ultrafiltration to get rid of the salts and glycerol, followed by precipitation with trichloracetic acid (Seibert *et al.* 1934). (See also Gough 1934.) Further work has resulted in the separation of a protein derivative with a molecular weight of only 10,500, containing very little nucleic acid and polysaccharide, and having twice the potency of the previous product (Seibert, Pedersen and Tiselius 1938, Seibert 1941*a*, *b*, Seibert and Glenn 1941). Though P.P.D. constitutes an advance on O.T., it is still far from perfect as a specific diagnostic agent. Successive preparations differ in potency, in specificity, and in antigenicity (McCarter and Watson 1942), so that standardization is just as necessary as with O.T. (For the chemistry of tuberculin, see Seibert 1944.)

Old tuberculin is most conveniently standardized against a standard tuberculin —hitherto issued by the Frankfurt Institute but now stored at the State Serum Institute, Copenhagen (see Report 1931*a*)—using the intradermal inoculation of sensitized guinea-pigs (see Okell and Parish 1927, Parish 1938).

This method, originally described by Römer (1909), consists in inoculating the tuberculin into the animal's flank. As many as 12 or 16 injections can be made on the depilated skin of the same animal. Twenty-four hours after injection a large papule is seen with a hæmorrhagic necrotic centre—the so-called cockade reaction. The reaction reaches its height after 48 hours, and later necrosis becomes more marked. Slight infiltration and swelling cannot be regarded as positive. Römer's test is positive about 3 weeks after infection. Dilutions of the tuberculin to be tested are compared with the standard tuberculin, and the relative potencies of the two products determined.

Tuberculo-protein preparations are standardized against old tuberculin, either by using the guinea-pig method or by making titrations on human subjects (see Lichtenstein 1934, Appel *et al.* 1934, Barnwell and Pollard 1934, Aronson 1934, Long 1934, Long *et al.* 1934).

The Reaction to Tuberculin.—Koch found that 2 ml. of old tuberculin injected subcutaneously into a normal guinea-pig had very little effect on it; but the injection of as small a quantity as 0·01 ml. into a tuberculous guinea-pig—infected 8 to 10 weeks previously—killed it within a few hours. Post mortem, the local lesion at the site of the tuberculin injection was very congested, and often dark or

almost violet in colour: the focal glands were also very congested: the liver and spleen, besides their tuberculous lesions, showed on the surface numerous punctiform dark red spots looking like ecchymoses, but which microscopically were found to consist of enormously distended capillaries in the neighbourhood of the tuberculous foci, filled with red blood corpuscles. That is to say, the effect of the tuberculin was to produce (1) a local lesion, at the site of injection: (2) a focal lesion, around the tubercles in the tissues: and (3) a constitutional reaction, terminating in death (see also p. 1161).

Analogous observations were made on man. A new-born infant, which has never come into contact with tuberculosis, can withstand the injection of 1 ml. of old tuberculin. A healthy adult, who has been infected, but who is not suffering from clinical tuberculosis, can withstand the injection of about 0·01 ml. without suffering from more than transient malaise and slight pains in the limbs. But the same quantity injected into a clinically tuberculous patient gives rise to a severe reaction, characterized by malaise, pains in the limbs, cough, dyspnœa, rigor, vomiting, and a high fever: the temperature begins to rise about 4 hours after the injection, reaches a maximum of 102° to 104° F., and passes off in 12 to 15 hours. As in the guinea-pig, the reaction is (1) local—an inflammatory reaction occurs at the site of injection (*Stichreaktion*): (2) focal—acute congestion occurs around tuberculous foci; this can be actually observed in lupus patients; an injection causes redness and swelling of the lesion, lasting for 2 or 3 days, followed by the formation of crusts of dried exuded serum, which drop off in 2 or 3 weeks leaving a clean red scar: (3) a constitutional reaction, already described.

The tuberculin reaction can be obtained not only in animals actually infected with the tubercle bacillus, but also in animals that have been injected with dead tubercle bacilli. Bessau (1916), for example, was able by the intraperitoneal injection of 1 mgm. of human tubercle bacilli killed by heat at 65° C. for 2 hours, or by the subcutaneous injection of 5–15 mgm., to produce a skin sensitivity to tuberculin in guinea-pigs; the tuberculin reaction was often as strong as in tuberculous animals. But this hypersensitiveness did not develop immediately; it took as a rule 2 to 3 weeks, and sometimes as long as 4 months, to develop. These observations have been frequently confirmed (Nakayama 1924, Zinsser and Petroff 1924, Lange and Freund 1926).

Unlike dead bacilli, old tuberculin, even after a long course of injections, usually fails to sensitize the guinea-pig (but see Aronson and Nicholas 1933). According to Seibert (1932), this is due partly to the fact that the dosage is inadequate, and partly to a diminution in the antigenic activity of the protein in old tuberculin as the result of the heat used in its preparation. Tuberculo-protein, on the other hand, if given in a total dosage of about 30 mgm., corresponding to about 60 ml. of pure tuberculin, is capable of bringing about typical skin sensitiveness in the guinea-pig. Rabbits can also be sensitized if larger doses are used, but the tuberculin reaction in the rabbit is less constant than in the guinea-pig, and not all tuberculous rabbits react to tuberculin (see Report 1913). It is very difficult to regard Seibert's explanation as wholly satisfactory, as she herself realizes. Why is it, for example, that guinea-pigs can be sensitized to tuberculin by a single dose of 0·1–0·5 mgm. of dead tubercle bacilli (see Tytler 1930, Douglas and Hartley 1934*a*), when it requires as much as 30 mgm. of purified protein to produce the same effect?

Bovine and human tuberculin appear to be similar in their toxic effects (Wolbach and Ernst 1904). Moreover, tuberculins prepared from strains differing in virulence have apparently the same potency (see Seibert and Morley 1933). There is evidence,

however, that human and bovine tuberculins are not identical; a difference between them can be detected by means of cross-anaphylactic reactions in the guinea-pig (see Lewis and Seibert 1931.)

Since dead bacilli are able to sensitize animals to tuberculin, some sensitizing substance, tuberculin or tuberculin-like, must be liberated from the bacilli in the tissues. These substances sensitize the cells of the body, which are then able to react more strongly to the subsequent injection of tuberculin.

The generalized tuberculin reaction has been held to differ from anaphylaxis in that (1) the passive transference of tuberculin sensitivity from an infected to a normal animal has never yet been satisfactorily demonstrated: (2) the focal reaction, which occurs in the immediate neighbourhood of foci of active tuberculous infection after the injection of tuberculin, has no counterpart in anaphylactic shock: (3) the reaction to tuberculin is delayed for some hours; in anaphylaxis the shock occurs directly after the injection: (4) after tuberculin there is a rise in temperature; in anaphylactic shock there is a fall in temperature (see Chapter 51).

It is doubtful whether much attention should be paid to these differences. Lewis and Seibert (1931), for example, have apparently been able to produce fatal anaphylactic shock in guinea-pigs by the use of tuberculo-protein in place of tuberculin (see also Enders 1929). The sensitizing dose was 0·1–15·0 mgm. and was given intraperitoneally; the "shocking" dose was 5–15 mgm. and was given intravenously. Similar shock could be produced by the intravenous injection of tuberculo-protein into tuberculous guinea-pigs. Passive sensitization was also successfully accomplished by the intravenous injection of guinea-pigs with the serum of other guinea-pigs that had been actively immunized by repeated inoculation with tuberculo-protein. Twenty-four hours after the receipt of the serum, the passively sensitized animals were inoculated with 10–15 mgm. of tuberculo-protein. Most of them died of shock within 5 minutes. The serum of tuberculous guinea-pigs, however, was unable to convey passive sensitization to normal animals. Lewis and Seibert believe that bacterial protein preparations are usually bad anaphylactogens, because in their native state they are very insoluble, and when brought into solution they are either denatured, altered, or hydrolysed, particularly if they are exposed to heat, cold, sunlight, acids, or alkalies. Ultra-filtration and precipitation with ammonium sulphate are free from these defects, and were used for the preparation of the tuberculo-proteins in the experiments just described. Most workers have used old tuberculin, which has been submitted to prolonged heating, and it is probable that their failure to obtain anaphylactic shock may be attributable to this cause. On the whole it seems likely that the differences between the generalized tuberculin reaction and the typical anaphylactic reaction are dependent far more on solubility and rapidity of absorption of the protein than on any fundamental differences in the nature of the two reactions. In this connection it is interesting to note that Brahic and Veyron (1939) found a striking parallelism between the reaction to the intradermal inoculation of tuberculin and that to histamine (see p. 1148). Patients giving a strong tuberculin reaction likewise reacted strongly to histamine, and those with a weak tuberculin reaction gave only a feeble histamine reaction.

The Relation between Allergy and Immunity

Of recent years, owing partly to the observations of Heimbeck and his Scandinavian colleagues on the development of tuberculosis in nurses and students, and partly to the observations on animals of Rich and his colleagues in the United States, the relation between allergy and immunity has been under active discussion. Two opposing views have been expressed, each based on circumstantial evidence. It must be our endeavour to present the two sides of the case as fairly as we can.

In the first place we must define our terms, because some confusion has arisen from lack of clarity in this respect. Rich, for example, defines allergy and immunity mainly in terms of results. If allergy is defined as a state in which the tissues are damaged and immunity as a state in which they are protected, then clearly allergy must be bad and immunity good. In so far as bacteriology is concerned, we would rather define allergy as a condition which may develop as the result of introducing bacteria or their products into the body, and which manifests itself as a heightened or accelerated inflammatory response towards a particular type of antigen or other related substance, irrespective of the balance of harm or benefit that the altered response confers on the allergic host. Acquired bacterial immunity may be defined, for our purpose, as a state of resistance of the host, partial or complete, specific or non-specific, towards a given bacterium or its products. The problem is to determine whether allergy, as just defined, plays any part in the resistance of the host to tuberculosis.

Observations on Human Beings.—Stimulated by Scheel's observations at the Ullevaal Communal Hospital at Oslo on the frequency of tuberculosis in probationer nurses, Heimbeck (1927, 1932, 1933, 1936) tested with tuberculin every nurse entering the hospital. The training course lasted three years and comprised a period of service in the tuberculosis wards. Of 905 probationers submitted to the von Pirquet test, 625 gave a positive and 280 a negative reaction. The tests were begun on January 1st, 1924, and up to the time of publication in 1936, 27 of the initially tuberculin-positive and 96 of the initially tuberculin-negative nurses are said to have developed tuberculosis; in the former group none, and in the latter group 10, died. Thus the incidence of tuberculosis was about 8 times as high in the negative as in the positive group.

From 1927 onwards Heimbeck endeavoured to protect the von Pirquet negative nurses by vaccinating them subcutaneously with B.C.G. (see p. 1337). As the result of this procedure many of the nurses developed a positive tuberculin reaction, but some did not. The two groups were followed up, and it was found that of 287 nurses who became von Pirquet positive, only 8 developed tuberculosis, whereas of 107 who remained negative, no fewer than 22 developed tuberculosis. The incidence of tuberculosis was therefore over 7 times as high in the negative as in the positive group.

From these observations Heimbeck concludes that allergy is an expression of immunity. Before accepting, however, these figures as conclusive, two points must be noted. Firstly, instead of following up initially positive and initially negative nurses over the same length of time, Heimbeck transferred in his analysis the initially tuberculin-negative nurses to the positive group within one year of their primary infection. The result of this was that if the nurse developed symptoms of tuberculosis within a year of her primary infection, she appeared among the initially negative group that became tuberculous. If, on the other hand, she remained perfectly well for a year after becoming von Pirquet positive, she went to swell the group of initially positive nurses who failed to develop tuberculosis. Since Israel, Hetherington and Ord (1941) found that the majority of tuberculous lesions in initially tuberculin-negative nurses occurred during the year following the appearance of a positive reaction, there seems little doubt that the effect of this transfer must have been to increase the disparity between the two groups and weight the odds in favour of the initially tuberculin-positive group. In the second place, the term tuberculosis comprised pleurisy, pulmonary infil-

tration, erythema nodosum, and glandular tuberculosis as well as manifest pulmonary tuberculosis. If we restrict ourselves to this last group of cases, with tubercle bacilli in the sputum, then we find that only 4 out of 27 patients in the initially tuberculin-positive group and only 13 out of 96 in the initially negative group who are said to have developed tuberculosis suffered from manifest pulmonary disease. This makes little difference to the comparison between the two groups, but it does give a very different picture of the incidence of tuberculosis in the Oslo nurses.

Observations similar to those of Heimbeck have been made by other workers on nurses and medical students. Those recorded by Kristenson (1933) and Scheel (1935) in Scandinavia, Rist (1939) in Paris, and Israel, Hetherington and Ord (1941), Brahdy (1941), and Zacks and Sartwell (1942) in the United States are in general consonance with the results obtained by Heimbeck, though the differences between the tuberculin-positive and tuberculin-negative groups were usually considerably less than those recorded by Heimbeck. On the other hand, Jacobson (1933) in Denmark, and Plunkett, Weber, Siegal and Donk (1940) in the Newark State school for mental defectives found little difference between the two groups; and Shipman and Davis (1933) in California and Würtzen and Sjørslev (1936) recorded results that were actually in favour of the tuberculin-negative group (see also Ljung 1939).

We may turn now to investigations carried out under very different conditions, namely among the mine labourers on the Witwatersrand (Report 1932*b*). These labourers, or "boys," came from native territories in which tuberculosis was endemic. On arrival at the mine, they were submitted to a cursory physical examination in order to eliminate those with obvious disease, and were tested intradermally with 0·1 ml. of a 1/5000 dilution of old tuberculin. Their after-history is summarized in Table 105.

TABLE 105

SHOWING PROPORTION OF POSITIVE AND NEGATIVE REACTORS TO 1/5000 TUBERCULIN DEVELOPING CLINICAL TUBERCULOSIS. (S. African gold miners.)

Type of Reaction.	Number.	No. developing Tuberculosis.	Incidence of Tuberculosis per 100,000.
(*a*) Negative	32,864	114	347
(*b*) Weakly or moderately positive .	57,236	391	683
(*c*) Strongly positive.	3,879	60	1,547
(*b* and *c*) Positive	61,115	452	738

It will be seen that the incidence of tuberculosis was more than twice as high in the positive as in the negative reactors, and that the stronger the reaction was to tuberculin, the greater was the liability to clinical tuberculosis.

Before concluding that these figures are in direct contradiction to those of Heimbeck, it is important to realize that the two populations concerned differed in several respects. Heimbeck's nurses had been physically examined before being enrolled as probationers and all those with a history or with symptoms of tuberculosis had been excluded. The South African "boys" had undergone a much less rigorous inspection. As a result, probably a number of the positive reactors were suffering from latent active lesions, which progressed under the severe physical exercise in the mines to manifest pulmonary tuberculosis. This interpretation is

borne out by the fact that one-third of the strongly positive reactors broke down within three months of their admission to the mines. It may be noted that, though the incidence of tuberculosis was higher in the positive than in the negative group of Rand labourers, the severity of the disease and the case-mortality rate were both considerably greater among the initially negative reactors. The lesions showed little or no tendency to fibrosis, and the disease became rapidly generalized, whereas in the positive reactors fibrosis occurred and the lesions often remained confined to the lungs. Thus, in 24 per cent. of tuberculosis cases in the negative group the disease ran a septicæmic course, as opposed to 4 per cent. in the strongly, and 5 per cent. in the moderately or weakly, positive tuberculin reactors.

Two more discrepant observations may be mentioned. Myers and Hermann (1934) in the United States found that children who were tuberculin-positive while at school developed tuberculosis during the next 10 or 12 years far more frequently than their tuberculin-negative classmates. Similar findings were recorded by Pope, Sartwell and Zacks (1939). Yet Zacks and Sartwell (1942) found that in a school for the feeble-minded the proportion of non-reactors who developed tuberculosis during a period of 10 years was 4 times as great as that of initially positive reactors. Finally, Levine (1941) found that in children under 6 years of age the mortality rate following exogenous infection was much the same in those who were previously tuberculin-positive as in those who were previously tuberculin-negative, suggesting that sensitization of the tissues did not render a subsequent infection either more or less dangerous.

We have quoted enough evidence to show that there can be no simple relationship between allergy and immunity in the human subject. Under one set of conditions the advantage is on the side of the allergic, under another set on the side of the non-allergic. Admittedly some of the data are not free from criticism. Among school children, for example, it is probable that those who react to tuberculin are more likely to be exposed to further infection in the future than those who fail to react and are probably living in homes free from infection. Nevertheless the recorded differences between the behaviour of tuberculin-positive and tuberculin-negative reactors are too great to be explained away by errors of this sort.

On the whole the evidence suggests that persons who have passed safely through their primary infection are less liable to develop manifest tuberculosis when exposed to fresh infection than are those with no previous experience of the tubercle bacillus. The degree of benefit they derive, however, from their allergic state is probably dependent on a number of factors of which we have only imperfect knowledge. On the other hand, when they are exposed to unfavourable environmental conditions, such as overwork, undue fatigue, inadequate nutrition, and insufficient sleep, in the absence of any unusual exposure to new infection, allergic patients are more liable to break down through endogenous infection than those who are non-allergic. Put more succinctly, in the heavily infected *milieu* of a tuberculosis hospital the advantage is with the allergic; in the less heavily infected but physically strenuous conditions of the mine or the factory, the advantage is with the non-allergic.

Observations on Animals.—Turning to the experimental study of allergy, we may start with the observations of Rich (1929, 1930, 1931, 1933*a*, *b*) and of his colleagues (Rich and McCordock 1929, Rich and Brown 1930, Rich, Chesney and Turner 1933, Rich, Jennings and Downing 1933, Rothschild *et al.* 1934).

Briefly, it was found that guinea-pigs which had been submitted to a mild tuberculous

infection and then desensitized by repeated massive doses of tuberculin were just as resistant to superinfection with virulent tubercle bacilli as control animals that had received the same primary infection but had not been desensitized. From this observation Rich concludes that allergy plays no part in immunity.

Numerous workers (for references see Wilson, Schwabacher and Maier 1940) have confirmed Rich's fundamental observation, but not all would agree with him in its interpretation. A great deal hangs on the meaning of allergy and of desensitization. Is it possible, for instance, to desensitize a tuberculous guinea-pig so completely that it can be regarded as non-allergic ? The experimental evidence seems to show that, though the skin reactivity may be practically, though only temporarily, abolished by massive doses of tuberculin, it is almost impossible to achieve and maintain this state without seriously impairing the health and life of the animals. It is therefore doubtful whether a true comparison has ever been made between completely desensitized and control animals.

Again it is to be questioned whether desensitization of the skin necessarily implies desensitization of other tissues. Freund (1929), for example, showed that young tuberculous guinea-pigs were just as sensitive as adult guinea-pigs to the intraperitoneal inoculation of tuberculin, even though they were practically insensitive to its inoculation intracutaneously ; and Hehre and Freund (1939) found that tuberculous rats, though developing no local inflammatory reaction after injection of tuberculin into the skin, nevertheless died of tuberculin shock.

Another difficulty is to know whether the liberal daily dosage with tuberculin necessary to maintain the desensitization of the guinea-pig's skin has any immunizing effect. Rich assumes that it has not. Experimental evidence, it is true, suggests that injection of tuberculin leads to no increase in resistance of the *normal* animal, but that in *allergic* animals it sets up a series of focal reactions which may confer on the tissues some degree of resistance to the invasion of tubercle bacilli.

The work of Lurie (1934) indicates that the destruction of avirulent tubercle bacilli which occurs in the internal organs is greatest when the maximum degree of hypersensitivity is reached. The observations of Freund and Opie (1938) suggest that, though there is no linear relationship between skin sensitivity and resistance to the intravenous injection of virulent tubercle bacilli, nevertheless animals that are moderately allergic at the time of infection usually prove most resistant. Our own observations (Wilson *et al.* 1940) point in the same direction. Thus we found that a moderate degree of allergy in vaccinated animals at the time of infection was more beneficial than a low or high degree, and that in both normal and vaccinated animals the survival time tended to be more or less proportional to the degree of skin sensitivity reached after infection. In this connection the observations of Lurie (1938, 1944*b*) are of special interest. Lurie found that in genetically resistant rabbits the skin was less permeable to Indian ink, and that skin sensitivity to tuberculin was more rapidly established after infection than in genetically susceptible animals. In other words, animals capable of developing the greatest degree of allergy after infection, and presumably of restricting the invasion of the bacilli, tended to have the greatest resistance. The corollary of this, namely that bacilli multiply most in the tissues of animals having a very low degree of skin sensitivity, has been reported by Woodruff and Kelly (1942).

Many years ago Krause (1925) and Willis (1925) showed that the dissemination of tubercle bacilli from a local cutaneous or subcutaneous infection was very much slower in the allergic than in the normal animal. The local fixation of tubercle bacilli may depend, as Rich appears to believe, on the presence of agglutinating antibodies ; but since carbon particles (Lurie 1936) and dye particles (Joyner and Sabin 1938) are similarly fixed, it is probable that a non-specific cellular mechanism is at work as well. The observations of Freund and Angevine (1938) indicate that tubercle bacilli may multiply at the site of fixation, and that the retardation of lymphatic invasion is therefore probably due to mechanical factors (see Chapter 47). The mechanism of fixation may be reinforced

by the presence of specific antibodies, which tend to accumulate at the site of inflammatory areas in allergic animals (Menkin 1939, Fox 1936).

Another characteristic which, according to Lurie (1939*a*, *b*, 1942), is more closely related to immunity than anything else, is the increased phagocytic power of the mononuclear cells in tuberculous animals. This is manifested both *in vitro* and *in vivo*, and appears to be independent of humoral antibodies. The mononuclear cells accumulate more rapidly at the local site of infection in vaccinated or tuberculous animals than in normal animals, and destroy the ingested tubercle bacilli more completely. How far this cellular sensitization may be regarded as part of the allergic response may perhaps be questioned, but we find it difficult to separate it from the heightened or accelerated inflammatory response that we regard as characteristic of the allergic state.

All of this evidence is compatible with the thesis that an accelerated response of the tissue cells to the tubercle bacillus or its products is of survival value to the host. This conclusion agrees with that reached by Menkin (1938) in his review on the rôle of inflammation in immunity. The beneficial effect of desensitization with tuberculin seems to us to lie not in abolishing allergy, but in converting a high into a low degree of allergy. The repeated doses of tuberculin set up minor inflammatory reactions around each tuberculous focus in the body, and these tend to retard dissemination of the tubercle bacilli and to prevent the rapid and destructive caseation in the internal organs which seems more prone to occur in very hypersensitive animals. It seems clear, however, that allergy is not the only mechanism concerned in immunity. Under the section on Heredity for instance, we have already referred to Lurie's (1941) observations on rabbits, in which he found that genetically resistant rabbits, besides developing a rapid and intense degree of allergy, were distinguished from susceptible animals by a low skin permeability and the power to form antibodies quickly and in high concentration.

Summarizing, we believe that the experimental and the field evidence suggest that immunity to tuberculosis is composite, and that allergy is one of the factors which often, though not always, contributes to its establishment. The fixation of the organisms that occurs at the site of infection in the allergic subject prevents rapid lymphatic dissemination and enables the sensitized mononuclear cells to ingest and destroy the invading tubercle bacilli more quickly than in the non-allergic subject. On the other hand, there is some evidence that in the internal organs the violence of the inflammatory reaction that occurs around tuberculous foci in the highly allergic subject may lead to such rapid tissue necrosis that the resulting caseous abscess may constitute a source of general toxæmia, or by rupturing into a bronchus, for example, may pave the way for secondary infection. In general, allergic subjects are probably less liable to develop clinical tuberculosis than those who have never been in contact with the tubercle bacillus, but there are numerous exceptions. Allergic persons, with latent active lesions, particularly if exposed to unfavourable environmental conditions, are sometimes more liable to develop clinical manifestations of disease than those who are completely non-allergic. In a highly infective environment, however, as in the tuberculosis wards of hospitals, the non-allergic are usually at a disadvantage. The relationship between allergy and the liability to develop tuberculosis is complex, and depends on a number of factors, of which the state of the lesions, the risk of exposure to infection, and the environmental conditions are probably among the most important (for general discussion on relation of allergy to immunity see Chapter 51).

Our knowledge of immunity to tuberculosis is very deficient. There is evidence to suggest that genetic resistance plays as important a part as the development of acquired immunity. Neither type is absolute; both are subject to fluctuations; and acquired immunity, in particular, rarely seems to be of a high order or of long

duration. The logical development of these conclusions will be dealt with in the next section.

THE PROPHYLAXIS AND TREATMENT OF TUBERCULOSIS

Prevention of Infection.—General hygienic measures include the prevention of spitting, except into a suitable receptacle, which can be sterilized or burnt; the prevention of coughing, except into a handkerchief; the segregation of advanced cases of open tuberculosis; the prevention of overcrowding; the protection of infants and children from contact with tuberculous parents; the pasteurization or boiling of all milk except that coming from tubercle-free herds; and education in personal hygiene and in diet (see Discussion 1935, Hart 1937). Whether the risk of infection indoors can be reduced by ultra-violet irradiation of the atmosphere, it is as yet too early to say; but Lurie (1944*a*), working with rabbits, has reported some success by this means.

In view of the conclusions reached in the last section we believe that avoidance of exposure to massive and repeated infection and unfavourable environmental conditions is of greater importance than the attempt to develop an acquired immunity. There has in the past been a great tendency to overlook the fact that tuberculosis is an infectious disease. Little or no attempt has been made to protect nurses, medical students, and doctors against the unduly high risk of infection that practice of their profession entails, with the result that the incidence of tuberculosis has been unnecessarily high among these classes of the population. Again, too rigid an interpretation of Koch's phenomenon has led to the conclusion that tuberculous patients cannot be re-infected, regardless of the possible danger that a highly allergic patient may incur from an acute local inflammatory disturbance of a pulmonary focus resulting from re-infection. Exposure to any disease, even those in which recovery is followed by a high degree of immunity, is always accompanied by danger, and is not justified except in such an instance as measles in which an attenuated attack can be ensured by appropriate serum treatment. The avoidance of unnecessary exposure to infection is particularly desirable in the case that we are now considering, where infection never seems to be followed by a high degree of immunity, and is sometimes followed by clinical disease from which complete recovery is uncommon.

The argument is sometimes advanced that tuberculous milk is not an unmixed evil. The tubercle bacilli that it contains are presumed to cause mild infections in infants and children which serve to protect them against subsequent infection with the human bacillus. This argument cannot be too strongly condemned. The bovine tubercle bacillus is no less virulent than the human (see Griffith 1925*b*), and many of the infections to which it gives rise are severe and fatal. The argument involves the assumption that the exposed population, as a whole, benefits from the development of an acquired immunity, and ignores altogether the process played by natural selection in weeding out the least resistant members of the population. Even if it were true, the price to be paid, in terms of lives and suffering, for any such advantage is far too high (see p. 1317 and Griffith 1925*b*, Report 1934). If acquired immunity is to be developed, let us at least endeavour to produce it in some more intelligent way, less fraught with danger of active disease and death.

Prophylactic Vaccination against Tuberculosis.—Numerous attempts have been made to vaccinate animals against tuberculosis. Koch (1897), using tuberculin R.,

stated that by giving large doses, about 2–3 mgm., he was able to immunize a considerable number of guinea-pigs, so that they withstood repeated injections of virulent tubercle bacilli without becoming infected. These results, however, have never been satisfactorily confirmed.

Koch likewise tested the immunizing value of tubercle bacilli boiled in dilute mineral acids or strong alkalies; other workers have simply boiled or heated them to 70° C.; others have treated them with glycerine or 25 per cent. lactose; Löwenstein used formalin, Loeffler applied dry heat, Rappin used sodium fluoride, Noguchi sodium oleate, Deycke and Much choline and neurine, but all without result. At a later date Dreyer treated the bacilli with formalin and subsequently extracted them with acetone and as a result the organisms lost their acid-fast property. This so-called *denatyl* vaccine has not been found of value for immunizing guinea-pigs (Bronfenbrenner and Straub 1925, Douglas, J. S. C. *et al.* 1927, Dreyer, Vollum, and Ammitzboll 1931) have reported favourable results from its use in the vaccination of cattle.

The general outcome of most of these attempts has been disappointing, and Calmette, in particular, has concluded that dead vaccines are useless for purposes of immunization. How far this conclusion is justifiable, it is difficult to say. Most of the earlier workers were undoubtedly hoping for the production of an immunity similar to that obtainable in certain other diseases. The knowledge that we have since gained shows that such a hope was unduly optimistic. Recent experiments, made mostly on guinea-pigs with heat-killed bacilli, suggest very strongly that vaccination with dead organisms does lead to a definite increase in the resistance of the animals to infection, as judged by comparison of mortality, average survival time, and certain other criteria, with those in control unvaccinated animals (Petroff 1927, Petroff, Branch, and Jennings 1929, Freund 1932, Hughes 1933, Westenrijk 1933, Branch and Enders 1935, Schwabacher and Wilson 1937, Opie and Freund 1937, Griffith and Glover 1939, Opie, Flahiff and Smith 1939, Smithburn 1939, Wells, Flahiff and Smith 1944), but this increase of resistance falls far short of absolute immunity.

An attempt to improve the antigenic quality of the vaccine has been made by Spahlinger (1932), who grows the bacilli on media containing proteins specific to the type of animal to be vaccinated, and allows them to die out naturally during a period of some months. Adequately controlled experiments with this vaccine have not yet been made, but there is evidence to suggest that it may have some action in raising the resistance of animals to infection (Report 1935*a*). The use of living virulent bacilli for vaccination was tried on a small scale by Webb and Williams (1911) (see also Baldwin and Gardner 1921), but was given up as being too dangerous.

Vaccination with the B.C.G. Strain.—Believing that dead tubercle bacilli are useless for purposes of immunization, and that acquired immunity depends upon the persistence in the body of living bacilli, Calmette introduced a living vaccine consisting of a bovine strain that had become avirulent as the result of several years' subculture on a glycerol bile potato medium. This B.C.G. (Bacille Calmette-Guérin) strain can be injected into animals without giving rise to more than a small retrogressive local lesion, and its presence in the body usually renders the animal sensitive to tuberculin. According to Calmette, calves and heifers vaccinated with 50 mgm. subcutaneously become resistant to tuberculosis, and during the following year are able to withstand an intravenous injection of 5 mgm. of living virulent tubercle bacilli, sufficient to kill unvaccinated animals in 2 months.

The success of his laboratory experiments led Calmette to the vaccination of human subjects. In order to forestall natural infection, he considered it important to vaccinate infants directly after birth. For this purpose he recommended 3 doses, each of 10 mgm., to be given by the mouth on alternate days during the first 10 days of life. Moreover, in order to prevent infection before immunity had become established, he recommended that the infant should be removed from all sources of infection for 2 months after vaccination.

This vaccine has now been tried out on an extensive scale with results that are extremely difficult to assess. The great difficulty is that, with one or two exceptions to be mentioned later, there has been a general failure to realize the necessity of comparing the vaccinated infants with a control group belonging to the same social class, brought up in the same environment, and treated in exactly the same way as the vaccinated group. The usual practice has been to compare the tuberculosis or general mortality in the vaccinated infants with the estimated mortality for non-vaccinated infants in similar surroundings or in the country as a whole. Such comparisons, as Greenwood (1928), Rosenfeld (1928), Wolff (1930*a*, *b*), and Berghaus (1930, 1931) have pointed out, are grossly unfair. In the first place no exact figures exist for the mortality in unvaccinated infants brought up in a tuberculous environment, and the estimates that have been made differ enormously. In the second place, the unvaccinated infants are not strictly comparable with the vaccinated group, partly because they are not kept sheltered from infection during the first 2 months of life, and partly because they receive less parental, medical, and nursing attention than those infants which, after vaccination, are kept under more or less continuous observation. For these reasons, the reproduction, even if it were possible, of the immense pile of data that has accumulated on this subject in France and French-speaking countries, would serve no useful purpose, since from a statistical point of view it is practically worthless.

The realization of these fallacies has now led to the institution by other workers of a few experiments in which an attempt has been made to provide a control group with which the vaccinated group can be more strictly compared. It must be noted that the difficulties of obtaining an absolutely identical control group are almost insuperable, and some allowance has therefore got to be made when considering the results. We have already (p. 1331) drawn attention to the favourable results recorded by Heimbeck following the vaccination of von Pirquet-negative probationer nurses with B.C.G. Similar results have also been obtained by Scheel (1935) with medical students. We may now briefly consider the data collected by other workers on the vaccination of infants.

Park, Kereszturi, and Mishulow (1933) in New York vaccinated infants born into tuberculous families with B.C.G., the vaccine being given by the mouth during the first 10 days of life. A control group of infants was left unvaccinated. The two groups were not strictly comparable, (1) because the vaccinated infants were removed from their parents for 1 month after immunization, while the control infants were left at home; and (2) because the control infants were rather more heavily exposed to tuberculous infection than the vaccinated group. Some of the infants were kept under observation for 5 years, but with most of them the observational period was shorter. Altogether 3 out of 239 vaccinated, and 7 out of 189 control infants died of tuberculosis. The non-tuberculous mortality, on the other hand, was considerably higher in the vaccinated than in the control group—in contradiction of Calmette's assertion that B.C.G. vaccination lowers both the tuberculosis and the general mortality. Another series of children from tuberculous families was vaccinated parenterally—the vaccine being given intracutaneously

or subcutaneously some time after birth. All the vaccinated children reacted negatively to tuberculin before immunization. Of the control children, some had a positive and some had a negative reaction. During the observational period none of the 150 vaccinated children died of tuberculosis. Of the 155 control children with an initially positive Mantoux reaction 5 died of tuberculosis, while of 269 control children with an initially negative reaction 4 died of tuberculosis. While admitting that the differences are not significant, the authors conclude that B.C.G. vaccination apparently confers some measure of protection against tuberculosis in early life. A further report was published by Koreszturi and Park in 1936. The tuberculosis mortality among 690 vaccinated children was 0·9 per cent. against one of 2·7 per cent. among 755 control children. The odds against an observed difference of this magnitude being due to chance alone were estimated at more than 100 to 1.

A similar experiment has been reported by Aronson and Dannenberg (1935), in which both white and coloured infants were observed. No data, however, are provided to indicate how the children were selected, or what degree of similarity existed between the control and the vaccinated groups. The vaccinated infants were given B.C.G. by the mouth during the first 10 days of life. Observations on the infants were made as far as possible at 3-monthly intervals during the first year, and at 6-monthly intervals subsequently. The results are summarized in Table 106.

TABLE 106

DEATHS FROM TUBERCULOSIS IN CHILDREN VACCINATED WITH B.C.G. AND IN A CONTROL GROUP. (Aronson and Dannenberg 1935.)

Type of Exposure.	Vaccinated Group.			Control Group.		
	No.	Mean Age at Time of Last Observation in Months.	Deaths from Tuberculosis.	No.	Mean Age at Time of Last Observation in Months.	Deaths from Tuberculosis.
Exposed to contact with tuberculous patients having a positive sputum	41	31·4	1	84	40	10
Exposed to contact with tuberculous patients having a negative sputum	15	28·3	0	45	39·3	2
Not exposed to known contact with tuberculous patients	14	—	0	38	—	0

The numbers are few, and it will be observed that the mean age at the time of last observation was higher in the control than in the vaccinated group. Since tuberculous mortality is higher in the second than in the first year of life, this may obviously have affected the control group unfavourably. The results, however, do suggest that B.C.G. vaccination tends to confer some protection against the risk of death from tuberculosis during the first year or two of life. Radiographical observations, moreover, showed that whereas only 16·6 per cent. of 36 vaccinated children in the first group had lesions in the lungs, 56·6 per cent. of 83 control children in the same group showed pulmonary lesions.

Neither of these investigations yielded very striking results, but both of them afford some evidence that B.C.G. vaccination may bring about a slight increase in resistance to tuberculosis. How far even this conclusion is justifiable, however, may be questioned. Levine, Vogel and Rosenberg (1938), for example, report the results of a study of 1,830 children of tuberculous families in New York City. Between 1926 and 1932 the children were divided into two equal groups, one of which was vaccinated with B.C.G., the other of which was not. The result of

this was that the children of the more intelligent and co-operative parents tended to be vaccinated and those of the careless and less intelligent parents to constitute the control group. From 1933 onwards, therefore, the children were vaccinated alternately without any selection whatever. The results are shown in Table 107.

TABLE 107

RESULTS OF B.C.G. VACCINATION BEFORE AND AFTER ALTERNATE SELECTION OF CONTROL AND VACCINATED CASES.

(Levine, Vogel and Rosenberg 1938).

Period.	Alternate Selection.	Vaccinated Group.			Control Group.		
		No.	Tuberculosis Deaths.	Tuberculosis Mortality. %	No.	Tuberculosis Deaths	Tuberculosis Mortality. %
1926–32.	No	439	3	0·7	527	16	3·0
1933–36.	Yes	383	6	1·6	361	4	1·1

In the first period the tuberculosis mortality of the controls was over 4 times that of the vaccinated children. In the second period no such difference was apparent. The authors draw attention to the necessity in carrying out comparative trials of this nature of selecting alternate children for vaccination, of studying the degree of exposure of each child to infection, and of carrying out an autopsy on every child that dies to learn the true cause of death. Without such precautions the results are liable to be misleading.

Even if we admitted the beneficial effect of B.C.G. vaccination, which we are not prepared to do, we should still have to decide what value it was likely to be in practice. Tuberculosis mortality has been falling so rapidly, particularly in the lowest age groups, that in this country it is now of very much less importance than it used to be. In 1937, for example, only 1·1 per cent. of the total infantile mortality was due to tuberculosis, and the chances against dying from tuberculosis during the first year of life were about 1,500 to 1. In face of such a slight risk, general vaccination of all infants with B.C.G. is out of the question. If vaccination is to be employed, it will have to be restricted to infants who are born into tuberculous families, and possibly to other classes of the population, such as nurses and medical students, who are exposed to a special risk of infection. The evidence, particularly of Scandinavian and American workers, suggests that vaccination is more effective if performed by the intracutaneous or subcutaneous than by the oral route, and that the degree of allergy resulting is higher. Parenteral vaccination is, however, not without its disadvantages. A cold abscess forms, which persists for months, and may sometimes break down and ulcerate through the skin. How long increased resistance is likely to last it is impossible to say, but Calmette himself advised re-vaccination at 3, 7 and 15 years of age. If re-vaccination is not performed, the immunity—if any—resulting from the primary vaccination will presumably wear off in a year or two. If, on the other hand, it is performed, there is a danger of setting up in a tuberculin-positive patient an acute allergic reaction, which may have serious results.

We may add that there is no evidence to prove that organisms of the B.C.G. strain may regain their virulence by residence in the body. The virulence of the

strain seems to be actually falling, and it is doubtful how long it will retain its protective properties. The Lübeck catastrophe, in which 72 out of 251 vaccinated infants died of tuberculosis (see Report 1935*b*), was almost certainly due to the contamination of the vaccine with another strain of tubercle bacilli. Animal experiments, with the exception of those on cattle (see p. 1347), have on the whole not given a very convincing answer to the prophylactic value of B.C.G. vaccination. Observations on guinea-pigs and mice have shown that B.C.G. vaccination has some beneficial effect, mainly in retarding the development of tubercle bacilli in the body and thus favouring the occurrence of a more chronic type of disease (Okell and Parish 1928, Schwabacher and Wilson 1937, 1938, Griffith and Glover 1939, Liebow, Burn and Soper 1940).

A few of the papers in the enormous bibliography that has now arisen on this subject may be quoted (see Calmette 1924, 1930, 1931, 1932, Calmette and Guérin 1924, Calmette *et al.* 1924, 1926, Weil-Hallé and Turpin 1925, Wilbert 1925, Gamna and Giordano 1926, Heymans 1926, Tsekhnovitzer 1926, Gerlach 1927, Kraus 1927, Petroff *et al.* 1927, 1929, Gerlach and Kraus 1929, Kraus and Gerlach 1929, Debré and Cofino 1929, Gerlach 1930, Begbie 1930, 1931, Neufeld 1930, Uhlenhuth and Seiffert 1930, Griffith 1931, Birkhaug 1933, Clawson 1933, Meiszner and Prausnitz 1934, Irvine 1934, Shaffer 1935, Naeslund 1935, Besta and Lemneberg 1935, Rist 1936, Kayne 1936, Holmgren 1936, Jonesco-Mihaiesti *et al.* 1938, Kostic-Jocksic 1939, Baudouin 1940, Cantonnet 1942, Etcheverry 1942).

Vaccination with the Vole bacillus.—It is too early to decide whether vaccination with bacilli of the murine type isolated by A. Q. Wells (1937) from tuberculous voles will play a part in vaccination of human beings against tuberculosis. The preliminary observations of Wells and Brooke (1940) on guinea-pigs and of Griffith and Dalling (1940) on guinea-pigs and calves suggest that it is capable of giving rise to a greater degree of immunity than the B.C.G. strain. The results of further tests will be eagerly awaited.

Therapeutic Immunization against Tuberculosis.—The introduction of tuberculin by Koch in 1890 was the first of a long series of attempts to cure tuberculosis by the use of vaccines of tubercle bacilli or their products. Koch's old tuberculin, which has already been described (p. 1327), gave rise to such severe reactions—both focal and constitutional—that it was for a time practically abandoned. It is now used chiefly for stimulating chronic cases of tuberculosis that have passed into a torpid state, in which neither advance of the disease nor progress towards recovery is occurring (Burnand *et al.* 1922). Extremely small doses are employed. Jaquerod (see Burnand *et al.* 1922) starts with 0·1 ml. of a 1/100,000 dilution of old tuberculin; he repeats the injection every 2 days, increasing the dose by 1/10 ml., provided the reaction is not too severe. After about 5 months the patient is able to withstand 0·5 ml. of the undiluted tuberculin; this dose is repeated 3 or 4 times, after which the treatment is finished. The fundamental rule of all tuberculin treatment is never to provoke a febrile reaction of any importance.

Starting from the observation that patients suffering from lupus seldom contract serious lung disease, von Aichbergen (1937) recommends the artificial production of lupus for the treatment of severe pulmonary tuberculosis. Virulent tubercle bacilli are rubbed on the scarified skin of the patient, and the inoculations are repeated as often as necessary. Lupoid or verrucous lesions appear and remain localized. No focal reactions have been observed in the lungs. Favourable results are claimed for this method of treatment.

Chemotherapy of Tuberculosis.

Rich and Follis (1938) and Buttle and Parish (1938) reported the results of experiments on guinea-pigs suggesting that sulphanilamide had a mildly favourable effect on the course of the disease; but Smithburn (1938) and Steinbach and Dillon (1939) working with sulphanilamide, and Dietrich (1938) working with prontosil, found no beneficial effect at all.

More recently Promin (sodium *p. p'*-diaminodiphenylsulphone-N, N'-diglucose sulphonate) has come under trial. Observations on guinea-pigs recorded by Hinshaw and Feldman (1941) and Feldman, Mann and Hinshaw (1942) seem to show that it is of therapeutic value, but the results so far obtained by its use in man have not been promising (Zucker, Pinner and Hyman 1942).

TUBERCULOSIS IN ANIMALS

Frequency and Bacteriology.—Tuberculosis is widespread throughout the animal kingdom. It is common among certain species of domesticated animals, and though rarely encountered in wild animals living under feral conditions, it is not infrequent among them when they are brought into captivity (see Griffith 1928*a*, *b*, 1939, Scott 1928, Scott and Beattie 1928). Cattle, pigs, and fowls are the most frequently affected of stock animals. According to Myers (1940) tuberculosis in fowls is more common than is generally supposed. Dogs and cats suffer not infrequently (see Hjarre and Herlitz 1936, Hjärre 1939), horses occasionally, and sheep apparently seldom.

Bacteriologically, human, bovine, and avian types are found with varying degrees of frequency (see Table 108 which has been compiled from the results of A. S. Griffith 1924, 1925*a*, 1926, 1928*a*, *b*, Stableforth 1929, Cornell and A. S. Griffith, 1930, Lovell 1930, Lovell and White 1940, 1941, Schwabacher 1934, and Hjärre 1939, together with some of our own results).

Cattle are almost invariably infected with the bovine type, usually from other animals, but occasionally from a tuberculous attendant (Bang and Jepsen 1936, Nielsen and Plum 1940, Hedvall 1942). The avian bacillus may give rise to localized lesions, particularly in calves (see Minett 1932, Gloyne 1933, Glover and Griffith 1934–35); it has been isolated from the sputum, milk, intestine, and mesenteric glands (Wolters 1931, Glover and Griffith 1934–35, Glover 1941). Pigs suffer from generalized and from localized infection with the bovine, and from localized infection with the avian and much less often the human type. Nearly all strains isolated from the horse have been of bovine type; but they are often atypical and of less than standard virulence for calves and rabbits (Griffith 1937*b*). In the dog the human type seems to be commoner than the bovine (see Lovell and White 1940); but all strains from the cat have proved so far to be of bovine type. Sheep may be infected with the bovine or avian type; in the United States Harshfield, Roderick and Hawn (1937) found the avian type in 25 out of 26 cases. Parrots kept as pets are usually infected with the human type, but those living in aviaries with other birds may be infected with the avian type (see Cobbett 1917). Fowls and most other birds are infected almost exclusively with the avian type of bacillus.

Tuberculosis of Cattle.—Tuberculosis is one of the most serious diseases of cattle. In this country it is extremely common. As already mentioned, about 40 per cent. of cattle react to the tuberculin test, about 40 per cent. of animals slaughtered in

public abattoirs show macroscopic lesions of tuberculosis, and about 0·5 per cent. of all milch cows excrete tubercle bacilli in their milk (Report 1932*a*, 1934, Savage 1933). The disease is common throughout Europe, but in North America it is very much less common. In the United States the proportion of tuberculin-positive animals has now been reduced to less than 0·5 per cent. as the result of a slaughter policy instituted by the Federal Government in 1917 (Myers 1940). In the tropics the disease is more frequent than has been generally supposed (Carmichael 1939).

The incidence of the disease increases with the age of the animal; it is uncommon in calves (see Gofton 1937), fairly common in bullocks and heifers, and very common in cows—particularly the older animals. Table 109, compiled by Delépine (see Cobbett 1917) on the basis of tuberculin tests controlled by post-mortem examination, will make this clear.

The organs most frequently infected in cattle are the lungs, pleura, and thoracic lymph glands; less often the lymph glands and organs of the abdominal cavity. Tuberculosis of the udder is frequent, especially in the later stages of the infection. According to Vallée (1905), who gives records of over 43,000 tuberculous cattle, pulmonary lesions were present in 75 per cent., and hepatic lesions in 28 per cent., of all cases of localized tuberculosis; in generalized tuberculosis the lungs were always invaded, and the liver was invaded in 83 per cent. of cases. It is important to realize that tuberculous cattle may excrete bacilli in their milk even though no

TABLE 109

evidence of disease of the udder, as judged by microscopical examination after death, is to be found (Report 1909, Gaiger and Davies 1933). Cattle form the chief source of infection for other domesticated animals.

Diagnosis of Tuberculosis in Cattle.—The diagnosis of tuberculosis in cattle follows much the same lines as that of human tuberculosis. An attempt may be made either to demonstrate tubercle bacilli directly in the animal's secretions or excretions, or to arrive at an indirect diagnosis by some form of immunity reaction, such as the tuberculin test, which, if positive, may be interpreted as evidence of infection. The direct method is restricted largely to the examination of sputum and milk. Sputum is not always easy to obtain, but if the cow has a cough, small particles of sputum can often be found on the wall of the byre opposite the animal's head (Riddoch 1903).

Demonstration of Tubercle Bacilli in Milk.—Microscopical, cultural, serological, and animal inoculation tests are available, the last method being the commonest and most delicate.

Microscopical examination is of value mainly for the milk of individual cows suspected of suffering from udder tuberculosis.

The most satisfactory method is to draw off quarter samples from the udder, and to spin each sample separately a short time at low speed, to spread a film on a slide, to fix and de-fat with a combination of heat, alcohol and ether, and to stain with carbol-fuchsin (see Cowan and Maddocks 1935). The work of Torrance (1922, 1927), Matthews (1931), and Davies (1933) has shown that tubercle bacilli in milk are generally associated with the presence of characteristic endothelial cell clumps. It is therefore only necessary to examine the film with a low power for the presence of these clumps, and to reserve the oil-immersion lens for films in which these clumps are present. The clumps themselves are not diagnostic of tuberculosis, but they afford a good indication of the locality of the tubercle bacilli in the film. It would appear that about 50 per cent. or so of milks from individual cows shown to contain tubercle bacilli by guinea-pig inoculation can be detected by the microscopic method (Cowan and Maddocks 1935).

Cultivation is not often used as a routine, since it is less delicate than the guinea-pig method and not as rapid as the microscopic method. It is suitable mainly for the milk of individual cows collected under aseptic conditions.

The sediment resulting from high-speed centrifugation should be treated with an equal volume of 15 per cent. HCl for 10–15 minutes, and inoculated on to suitable media (see Wolters and Dehmel 1931).

The main value of the method seems to be in the occasional detection of the avian tubercle bacillus, which might be missed by the animal inoculation method.

Serological methods are still in the experimental stage. German workers have reported favourably on the value of the complement-fixation test carried out on the milk whey in the diagnosis of udder tuberculosis (see Karsten 1933, 1935, Sontgen and Menck 1933, Rautmann 1934, Rautmann and Hartwigk 1934, Schultz 1937, Paarmann 1936, Kuhlmann 1936), but there is little evidence to suggest that they furnish a reliable index of the infection of the milk.

Guinea-pig inoculation constitutes the most generally useful and most delicate method of detecting tubercle bacilli in milk.

About 50–100 ml. of milk, either mixed or from individual animals, should be centrifuged at 3,000 r.p.m. for 30 minutes, after removal of the gravity cream. The sediment and the cream should be mixed, and 3 ml. of the mixture should be injected intramuscularly into the left thigh of each of two animals, which should previously have been shown to be free from tuberculosis by means of the intradermal tuberculin test. One animal should be killed 3–4 weeks after inoculation; if the results are negative, the other animal should be left for 6–8 weeks. The post-mortem appearances of animals inoculated with tubercle bacilli have already been referred to (p. 1325), and it need only be mentioned here that no animal should be regarded as tuberculous unless characteristic lesions containing acid-fast bacilli are demonstrated.

The Tuberculin Test in the Diagnosis of Cattle Tuberculosis.—This test may be carried out in a number of different ways, but each method consists in noting a reaction, local or constitutional, to the injection of tuberculin. In this country the double intradermal test is generally used, but in the United States the single intradermal test, made by inoculating tuberculin into the skin of the caudal fold, is officially recommended. For the full technique of the double intradermal test the following references may be consulted (Report 1925, Buxton and MacNalty 1928).

Briefly the test consists in injecting 0·1 ml. of old tuberculin into the deeper layers of the dermis of a shaved area on the side of the neck. The animal is examined 48 hours later, and if a large diffuse œdematous swelling is found, hot and tender, the reaction is regarded as positive. If no more than a pea-like swelling is present, a second injection of 0·1 ml. should be made into the centre of the nodule, and the animal should be inspected after a further 24 hours. The true criteria of a positive reaction are swelling, heat, and tenderness, and as these are liable to variation, the interpretation of the test demands considerable experience.

A positive tuberculin reaction generally denotes that the animal contains a tuberculous focus somewhere in the body. It gives no information on the activity of the focus. The test is used mainly to determine whether the animal is *infected*, not whether it is *infective*. A negative reaction, while not absolutely excluding the presence of infection, is strong evidence against it. The test has been severely criticized by a number of workers, and there is no question that it is not entirely satisfactory. The presence of infection with avian tubercle bacilli, which appears to be not uncommon, is sufficient to give rise to a positive reaction, even though avian bacilli rarely cause more than a localized, retrogressive type of tuberculosis. Similarly, a reaction may sometimes be obtained in animals showing skin infiltrations and nodules due to an acid-fast bacillus different from the tubercle bacillus; this condition has been described in the United States (see Daines and Austin 1934) and in Great Britain by Robertson and Hole (1937). The test, it will be understood, is not absolutely specific for tuberculosis, and is often given by animals containing insignificant foci of disease. Border-line reactions are not infrequent; possibly the replacement of old tuberculin with a purer type of tuberculin may

diminish the difficulty caused by non-specific reactions (Montgomerie and Thomson 1939). In careful hands, however, it is of very real value, and is indispensable in the detection of tuberculous infection (see Teipel 1925, Ernest and Lash 1928, Haring and Traum 1929, Hastings *et al.* 1930, 1933, Mohler 1931, Fowler and Wright 1931, Glover 1932–33, Buxton and Glover 1932–33, Minett 1932, McEwen and Roberts 1934, Cabot 1938, Montgomerie and Thomson 1938, Parish 1938, Buxton and Glover 1939).

Control of Tuberculosis in Cattle.—Opinions on the measures to be taken to control tuberculosis in cattle are very divided. In this country (see also p. 2050) and in Germany the practice has been to rely mainly on the detection of tuberculous animals by clinical inspection, combined with bacteriological examination of the milk, and to remove all open cases of disease. Though this method may, if prosecuted with real thoroughness, bring about a diminution in the total number of animals suffering from open tuberculosis, it probably has little or no effect on the total incidence of infection. The reason for this, of course, is that by the time a tuberculous animal has been diagnosed by the methods just described, it has already been excreting tubercle bacilli for some time and has acted as a focus of infection for other animals in the herd. In Germany and Switzerland the similar but more thorough method of von Ostertag (1913, 1936) has been used; this makes use of bacteriological examination for the detection of animals showing no clinical evidence of tuberculosis. The method claims not to eradicate the disease, but to pave the way for the slaughter policy based on the tuberculin test (see Brook 1937).

In the Scandinavian countries, largely owing to the initiative of Bang (see Bang 1928, 1929, 1930, 1932), and in the United States and Canada, a more radical method has been adopted, aiming at the elimination not only of open cases of tuberculosis, but of all animals infected with the tubercle bacillus. The general method is to test every animal in the herd with tuberculin, to segregate, remove, or slaughter the positive reactors, and to build up the herd exclusively from negatively reacting animals. The tuberculin test must be repeated at 3- or 6-monthly intervals to detect any fresh reactors in the clean herd. This method, if accompanied by complete removal or slaughter of the reacting animals, is often highly successful in eradicating tuberculosis and in maintaining a tuberculosis-free herd. In the United States, for example, the proportion of animals reacting to tuberculin was reduced between 1917 and 1940 from an average initial rate of about 4 per cent. to one of about 0·5 per cent. (Myers 1940). Where segregation alone is practised, and two herds are kept on the same farm (Bang's method), the results are less satisfactory.

The respective merits of the different methods of controlling tuberculosis in cattle cannot be fully discussed here; opinion is sharply divided upon them. The eradication method is undoubtedly much the more effective, and should be recommended whenever sufficient money is available to meet the cost. The cost, however, is a very real consideration, and many agriculturists regard tuberculosis as of insufficient economic importance to justify a radical scheme. They would rather rely on the rapid detection of open cases of tuberculosis, and the restriction of the herd to comparatively young animals, in which the disease is less frequent than in the older animals (see Table 109, p. 1344). The question must be decided by the agriculturists themselves. From the point of view of human medicine, safeguarding of the milk supply is much more satisfactorily effected by pasteurization than by

reliance on any eradication scheme (see Haring 1929, Mohler *et al.* 1929, Hutyra 1929, Günzel 1929, Glover and Spencer 1930, Seiferle 1930, Regler 1930, Heath 1930, Wight 1930, Kiernan and Wight 1930, Jordan 1933).

Vaccination of Cattle against Tuberculosis. If an eradication scheme is impracticable, it is clearly desirable to aim at the diminution of advanced and open cases of tuberculosis. Besides the measures already discussed for this purpose, the possibility of vaccinating the animals so as to raise their general level of resistance to tuberculous infection has long occupied the minds of veterinary and other workers. Von Behring introduced the method of vaccinating calves with living bacilli of the human type. The method was successful in rendering the animals allergic, and fairly successful in protecting them—for a few months at least—against natural tuberculosis; but it had to be discarded, since it was found that the bacilli remained alive in the tissues and were excreted by the milk, which was, of course, dangerous for human beings (Report 1911*c*, Griffith, A. S., 1912–13, 1916–17). Attempts have been made to vaccinate cattle with avian bacilli, but the results have not been so successful—probably because avian bacilli do not set up the same focal lesions in cattle that human bacilli do (M'Fadyean *et al.* 1913, Gamna and Giordano 1926). Friedmann introduced his turtle bacillus for vaccination, but this organism was found to provide little or no protection for warm-blooded animals.

More recently the claims put forward by Calmette for his B.C.G. vaccine have attracted considerable attention. Many different workers have now carried out experiments to test the prophylactic value of this vaccine. Since the technique of different workers has varied very considerably, it is impossible to summarize quantitatively the results that have been obtained, and we must refer our readers to the original papers in which they are described (see Watson 1928, 1930, Schroeder and Crawford 1928–29, Rankin 1929, Rankin *et al.* 1932, Haring *et al.* 1930, Bang, O. *et al.* 1931, Cotton and Crawford 1932, Jundell and Magnusson 1933, Buxton and Griffith 1931, Griffith, Buxton, and Glover 1931, 1935, Buxton, Glover and Griffith 1934–35, Ascoli 1936, Buxton 1936, Buxton *et al.* 1939).

The results, however, are sufficiently concordant to justify a few tentative general conclusions. There seems to be little doubt that if B.C.G. is given to uninfected calves shortly after birth, preferably by the parenteral route, their resistance both to experimental and natural infection with the tubercle bacillus is definitely increased compared with that of unvaccinated control animals. The immunity produced is by no means absolute, and does not seem to be sufficient as a rule to prevent actual infection from occurring. It is, however, often sufficient for a time to keep the infection from becoming active. There is evidence that the immunity resulting from the primary vaccination gradually diminishes with passage of time, and wears off to a greater or less extent after 12 months. Re-vaccination may partially restore the lost immunity, but there is not yet sufficient evidence to justify an opinion on its real value.

From these results it is clear that vaccination of calves with B.C.G. deserves a trial under field conditions. Whether the limited increase in immunity that it is likely to produce will be sufficient to bring about any considerable diminution in the number of active cases of tuberculosis among animals that are exposed to frequent infection from their fellows, it is impossible to predict, and we must await the verdict of actual experience. It is important to realize that B.C.G. vaccination renders the animal allergic, so that the tuberculin test can no longer be used to indicate the presence of infection with virulent bacilli. B.C.G. vaccination is

therefore incompatible with an eradication policy. The promising results obtained by Griffith and Dalling (1940) in the vaccination of calves with the vole strain of tubercle bacillus have already been referred to (p. 1341).

Mention may perhaps be made of the Spahlinger vaccine (see p. 1337) which has been credited with some success in preliminary experiments in the North of Ireland (Report 1935*a*).

Tuberculosis of Pigs.—The exact incidence of this disease is unknown, but slaughter-house records leave no doubt of its frequency in this country. Ellison (1930) found that 12·09 per cent. of 72,350 pigs supplied to a bacon factory at Ipswich showed macroscopic lesions of tuberculosis. Other figures showed that 7·6 per cent. of 44,000 pigs coming into another bacon factory over a period of 2 years contained lesions of tuberculosis (Report 1933*b*). The glands draining the alimentary tract are mainly affected, particularly the submaxillary and mesenteric group. In about 84 per cent. of carcasses in Ellison's series the lesions were confined to the head and neck, and in about 5 per cent. to the plucks or offal or both. In only 0·15 per cent. of animals was the disease generalized or advanced.

The bovine type of tubercle bacillus is found in about two-thirds and the avian bacillus in about one-third of the cases ; the human tubercle bacillus is very much less common (Griffith, A. S., 1928*a*, Cornell and Griffith 1930). Submaxillary glands infected with avian or human bacilli are often not appreciably enlarged, and contain discrete caseo-calcareous tubercles ; those infected with bovine bacilli are generally enlarged and composed wholly or in part of caseous or caseo-calcareous material surrounded by fibrous tissue. Generalized tuberculosis is almost invariably due to the bovine type.

Pigs become infected from various sources, the chief being raw cow's milk, infected cow dung, slaughter-house offal, and the droppings of tuberculous fowls. Infection occurs by the mouth. The disease can be diagnosed during life by the intradermal inoculation of tuberculin into the ear, but in most animals infection is not diagnosed, and often not even suspected, till they come to the abattoir. Prevention consists in avoiding contamination of the food with tubercle bacilli ; boiling all food, including milk, that may possibly be infected ; and keeping the animals separate from tuberculous cattle and poultry (see Mohler and Washburn 1930). In the United States an active campaign based on the tuberculin test is now being waged against the disease (Myers 1940).

Tuberculosis in Fowls.—Comparatively little is known of the frequency with which tuberculosis attacks fowls in this country. It is met with in farmyard birds, but is uncommon on poultry farms. In Germany, however, Klimmer (quoted by Knorr 1932) stated that of 75 million hens, 7½ million were tuberculous, and that 3 per cent. of market eggs, and 10 per cent. of eggs from tuberculous hens, contained tubercle bacilli. In the United States a survey of 115,700 flocks of poultry in 40 States revealed the presence of tuberculosis in 6,690 (5·8 per cent.) ; the actual number of fowls affected was estimated at over 8 million (Mohler and Washburn 1930). The highest incidence of infection occurs in the north central states. Disease is much commoner in old birds than in young (Feldman 1938). The organs most frequently affected are the liver, spleen, intestines, lungs, bones, joints, peritoneum, kidneys, and ovary (Gallagher 1926). The disease can be diagnosed by the intradermal tuberculin test using avian tuberculin. The slaughter policy seems to be the most suitable method of dealing with the disease when it is extensive, but an eradication plan based on the use of tuberculin may be tried

if the disease is less extensive or the birds valuable. (For a general survey of avian tuberculosis see Gloyne 1933, Feldman 1938.) Acid-fast organisms have been reported in bumble-foot of chickens, but their exact nature is unknown (see Bunyea 1936).

CHAPTER 60

LEPROSY, RAT LEPROSY, AND JOHNE'S DISEASE

LEPROSY

History and Epidemiology.—Leprosy is a disease of great antiquity; when or where it originated is not known, but according to Rogers and Muir (1925) it is probable that the original focus was in the northern belt of Central Africa. The disease was described in Asia Minor about 345 B.C.; thence it spread gradually westwards, till in the Middle Ages practically every country in Europe was affected. During the fourteenth and fifteenth centuries leprosy in Europe declined rapidly; about the same time, however, it was carried to the Western Hemisphere. During the last 70 years the disease has appeared in Oceania, where it has spread widely; in Hawaii, for example, it was estimated in 1909 that 1 in every 40 natives was a leper (Brinckerhoff and Moore 1909).

At the present time the highest incidence of the disease is confined to tropical countries, particularly (1) Equatorial Africa; (2) the long belt stretching from Assam and Burma, through the Malay States and Indo-China to the islands of the Pacific; and (3) the West Indian Islands and the northern part of South America. Males appear to be more commonly affected than females. Infection seems to be most frequent in youth and early adult life; Rogers and Muir (1925) state that probably over 50 per cent. of cases are infected before the age of 20. The lower social classes are more frequently infected than the higher. The incubation period may be almost any time, from a few weeks to several years; the commonest period is 2 to 4 years, but it is said that it may extend even to 40 years. The disease is extremely chronic and may be of lifelong duration; after it has lasted for a variable length of time it may retrogress as the result of a naturally acquired immunity; on the other hand, after remaining chronic for years, it may take on an acute course. The mortality from the disease itself is comparatively low.

The way in which leprosy is conveyed is uncertain. Most workers are agreed that it is infectious, but the manner in which infection is spread is still largely a matter of conjecture. Considering the long incubation period of the disease, this is not surprising. The restriction of the lesions to the skin suggests that the bacilli gain entrance through cuts, abrasions, and fissures, but it is possible that the nasal mucosa may be primarily infected. Lepers suffering from the tubercular form are very much more infective than those suffering from the anæsthetic form; this is because lepra bacilli are numerous in the nodules of the skin, but are uncommon in the anæsthetic patches. Blood-sucking flies and other insects have been suspected as carriers of infection, but no convincing evidence against them has been brought forward. On the whole the infectivity of the disease

is low; close and long-standing contact with lepers has generally to be maintained before infection is contracted.

The **bacteriology** of the disease has already been described in Chapter 16.

Experimental Reproduction of the Disease in Animals.—A few workers claim to have reproduced leprosy in monkeys.

Nicolle in 1905 inoculated two bonnet monkeys subcutaneously in front of the left ear with ground-up tissue from a patient with generalized nodular leprosy. A nodule appeared 62 days later at the site of inoculation, and a fortnight after its appearance it was partly excised; histologically it consisted of several small nodules made up of lymphocytes and mononuclears; there were no giant cells and no caseation; lepra bacilli were present in moderate numbers, almost exclusively within the cells. Inoculation by scarification of the skin, or by rubbing on to the nasal and conjunctival mucosa, was without effect. More recently, Reenstierna (1926) inoculated two monkeys (*Macacus sinicus* and *M. rhesus*) with a suspension of ground-up lepromata from two untreated patients with generalized nodular leprosy; the inoculations were made in the supraorbital and malar regions of both sides of the face, into both nostrils, and in the pubic region. On the 39th day, a small, round, hard nodule was visible over the right malar bone; similar swellings appeared later over the other sites of inoculation, with the exception of the nasal mucosa, which remained intact. The nodules increased till the 70th day, when they varied in size from a small pea to a nut. Pieces were excised from some of these and injected into guinea-pigs and monkeys; both sets of animals remained well. Microscopically, the nodules consisted of granulation tissue with large mononuclear cells, often vacuolated, containing leprosy bacilli. Shortly after excision of the nodules, the remaining lesions began to decrease in size; ultimately they disappeared. Similar results were obtained with 6 other monkeys. The nodules appeared in 5 to 8 weeks, sometimes reached the size of a small plum, and disappeared as a rule in 6 to 10 weeks. Passage experiments were unsuccessful. Soule and McKinley (1932) likewise found that *Macacus rhesus* and *Cebus olivaceus* monkeys, inoculated intradermally over the eyebrow, developed firm, hard, nodular swellings in 18–20 days, which increased gradually in size for 10–14 days, then retrogressed, and disappeared entirely within another 3 or 4 weeks. The injection of pure cultures, made according to their technique, also resulted quite frequently in the production of transient nodular lesions (see also McKinley 1934).

There appears to be little doubt from these experiments that a localized form of leprosy can be conveyed to monkeys by inoculation of leprous material; but the disease is transient and rapidly cures itself.

More recent observations suggest that some cases at least of human leprosy are caused by the *rat leprosy bacillus*. In 1922 Marchoux (1922, 1933) reported the production of a disease in rats, indistinguishable from rat leprosy, following the injection of a splenic suspension containing abundant acid-fast bacilli from a young Haitian who died from a disease diagnosed as leprosy. Little attention was paid to this finding until Adler (1937) in Palestine, following up the observation of Balfour-Jones (1937) (see also Laidlaw 1937) that rat leprosy could be conveyed to the Syrian hamster (*Cricetus auratus*), described the successful transmission of infection to three of these animals by the inoculation of material from leprosy in man. The following year Burnet (1938*a*, *b*) recorded the production of leprosy in 1 out of 6 hamsters inoculated with human material; and in 1939 Burnet and Jadfard reported one further successful inoculation. Dubois and Gavrilov (1943) inoculated 16 hamsters with material from 12 cases of leprosy; one of these animals developed rat leprosy. The interpretation of these findings is still not clear. Until further work has been carried out, and until the frequency of

natural infection of the Syrian hamster with the rat leprosy bacillus has been ascertained, it would be rash to do more than suggest that this organism may be responsible for occasional cases in man.

Diagnosis.—In the tubercular form, a piece of skin over one of the nodules should be examined microscopically for leprosy bacilli (Fig. 280). With a sharp pair of scissors curved on the flat, a piece of skin 3 mm. long and 2 mm. deep is clipped off the surface. The corium is pressed downwards on to a clean new slide, and a film preparation made, and stained with Ziehl-Neelsen (Rogers and Muir 1925); or the skin may be fixed, embedded in paraffin, and sections cut in the usual way. If acid-fast bacilli cannot be found in the nodules, it is advisable to examine the nasal mucosa. The most satisfactory method is to scrape the mucosa gently with a blunt scalpel, and make ordinary film preparations. The bacilli can frequently be demonstrated in this situation in the tubercular form, and may be found in some cases of the anæsthetic form of the disease. Sometimes they are present in the nasal mucosa before skin nodules have developed; thus they are said to be demonstrable occasionally in apparently healthy contacts. In early cases of generalized leprosy, the bacilli can often be demonstrated in clippings from the lobule of the ear. If there is any doubt as to whether the organisms found in the nose or skin are true leprosy bacilli, it is advisable to inject a suspension of the ground-up material into guinea-pigs; if they are leprosy bacilli, there will be no result; if on the other hand they are tubercle bacilli, the animals will develop the usual form of experimental tuberculosis.

When the lungs are affected, the sputum may contain lepra bacilli, which are most easily distinguished from tubercle bacilli by animal inoculation.

The complement-fixation test has been employed for the diagnosis of leprosy, but it does not appear to be of much value in practice, since a positive reaction may be obtained with antigens made from tubercle bacilli (Row 1925–26).

Lepers frequently give a positive Wassermann reaction; doubtless this is often due to the co-existence of syphilis, but there appears to be little doubt that the Wassermann reaction may be positive in leprosy in the complete absence of syphilitic infection. In countries in which the positive Wassermann reaction rate varies from 7 to 20 per cent. amongst the general population, many observers have found that the rate amongst lepers varies from 15 to 95 per cent. (Rogers and Muir 1925). The great variation in the percentage of positive reactions amongst the leprous population seems to depend largely on the type of antigen employed. Thus Hasseltine (1924) examined the serum of 236 lepers in Hawaii. Using an acetone-insoluble antigen he obtained 17·8 per cent. of positive results; with an antigen consisting of an alcoholic extract of beef heart to which 0·4 per cent. of cholesterol had been added, he obtained 50 per cent. of positives; and with Kolmer's (1922) new antigen he obtained 21·6 per cent. of positives. The greatest number of positive reactions occurred in lepers with the nodular type of

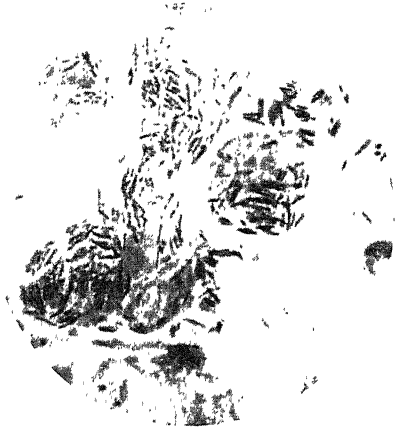

FIG. 280.

Leprosy bacilli in the tissues. The bacilli are seen in dense clumps, mostly intracellular (× 1000).

disease, the smallest number in those with the anæsthetic type. In each form, lepers in the advanced stage of the disease gave more positive results than those in an early stage. Of the general population about 12 per cent. showed evidence of syphilis. It seems clear from these findings that (i) a large number of undoubted lepers give a negative Wassermann reaction, even when a highly sensitive cholesterolated antigen is used; (ii) if a cholesterolated antigen is used, a higher proportion of lepers react positively than when an acetone-insoluble antigen without addition of cholesterol is used. Hasseltine found that many lepers with a positive reaction improved under anti-syphilitic treatment. In the differential diagnosis of leprosy and syphilis, he regards a positive reaction with an acetone-insoluble antigen or with Kolmer's antigen as strong presumptive evidence of syphilis; in the absence of definite evidence of leprosy, such patients should be given anti-syphilitic treatment before being declared lepers. Fletcher (1915), working in the Federated Malay States, obtained 13·6 per cent. of positive Wassermann reactions in lepers with no history of syphilis, and only 3·4 per cent. in non-lepers who also had no history of syphilis. The luetin skin test was uniformly negative in leprosy, even when the Wassermann reaction was positive. Since the luetin test may be negative when the Wassermann reaction is positive, and more positive Wassermann reactions occur in lepers than in non-lepers, Fletcher concludes that leprosy itself may be responsible for a positive Wassermann reaction.

Attempts to diagnose leprosy by means of a specific allergic reaction with a substance known as *lepromin* (Bargehr 1926), or with other substances derived from acid-fast bacilli, have not proved successful (McKinley 1938).

Prophylaxis and Treatment.—The prophylaxis of leprosy is at present a hygienic problem, and rests on the detection and isolation of infected persons, and on their adequate control.

In the treatment of leprosy, vaccines of several different types have been used. Tuberculin was tried as early as 1891, but without result. Nastin is a preparation made by ethereal extraction of an acid-fast streptothrix, and used largely by Deycke; the results do not appear to be very promising. Vaccines have been prepared from the numerous acid-fast bacilli isolated from leprous lesions, also without any marked benefit. With all these vaccines a certain number of patients improve temporarily, but this improvement seems to be largely due to a non-specific reaction, and is most marked when a severe constitutional reaction is produced. Several workers have used the bacilli present in lepra nodules. Hasson (1925–26), for example, employs a vaccine consisting of an autolysate of lepra bacilli, obtained from artificial blisters in lepers, mixed with *Ps. pyocyanea*; this latter organism is added to provoke a febrile reaction. His own reports were very favourable; improvement was said to begin after the third injection, and to be progressive. Patients treated for 18 months had not relapsed. It is doubtful how far this treatment is specific; Row (1925–26) states that he has observed great improvement by the use of a vaccine consisting of autolysed tubercle bacilli.

RAT LEPROSY

Rat leprosy is a disease that was first described by Stefansky (1903) in 1901 at Odessa. Rats were being slaughtered in large numbers, consequent on the outbreak of human plague, and rat leprosy was found in 4–5 per cent. of them. The incidence reported by other observers varies considerably.

In the United States McCoy (1913) found it in 186 out of about 200,000 rats caught in San Francisco, Cal., an incidence of 0·093 per cent.; and Wherry (1908) found it in

20 out of 9,631 rats caught in Oakland, Cal., an incidence of 0·21 per cent. In Japan, Ota and Asami (1932) found it in 0·7 per cent. of *Rattus norvegicus* and in 0·1 per cent. of *Rattus rattus*; and Yamamoto, Sato and Sato (1936) found it in 1·24 per cent. of 2,573 rats caught in Tokyo. According to Marchoux (1933), about 5 per cent. of the sewer rats in Paris harbour rat leprosy bacilli in the lymph nodes, but in only about 0·6 per cent. of the rats are generalized lesions present. In Batavia 9·3 per cent. of about 10,000 rats were said by Lampe and de Moor (1936) to have lesions of the lymph nodes, but not more than 0·23 per cent. of the animals had manifest skin leprosy.

The disease exists in two forms—the glandular type and the musculo-cutaneous type—but there appears to be no sharp division between them. In the *glandular type* one or more of the groups of subcutaneous glands—inguinal, axillary, or cervical—is enlarged, hard, and of whitish colour. On section the glands are uniform and hard; there are no nodules or necrotic areas visible macroscopically. Microscopically, the capsule and trabeculæ are thickened; the sinuses are filled with dense aggregations of irregularly polygonal cells, which have a large nucleus and much cytoplasm—probably macrophages; the cytoplasm is packed with acid-fast bacilli, so that the contours of the cell-body are often invisible. A few giant cells, with several peripheral nuclei, containing numerous bacilli in their cytoplasm are also visible. Some organisms may be found free.

In the *musculo-cutaneous type* the rat is emaciated; the skin presents one or more irregularly round or oval areas of alopecia, commonest on the head; occasionally ulcers are seen, about 0·5 cm. in diameter, covered with a mealy-looking discharge containing acid-fast bacilli. At the site of these areas of alopecia the skin is atrophic. The subcutaneous tissues are devoid of fat, and show the presence of a greyish-white, granular material, which Stefansky regards as altered muscle tissue; it contains numerous acid-fast bacilli. Sometimes nodular masses are found in the muscles, covered with particles of stretched atrophic skin. Stefansky believes that the primary lesion begins in the subcutaneous muscle fibres, and sometimes spreads to the skeletal muscles. Histologically, numerous acid-fast bacilli are found in the corium and subcutaneous tissue; some are free, but most are situated in the cells of the granulation tissue, and in large cells rich in cytoplasm, which resemble the lepra cells of Virchow, but contain no vacuoles. Acid-fast bacilli invade the muscle fibres, collect around the nuclei, and lead to destruction of the tissue. Lesions of the internal organs are rare; but McCoy (1913) states that nephritis is very common; the kidneys are enlarged, yellowish-brown, friable, and often cystic, but no acid-fast bacilli are found in them. In an examination of 186 leprous rats, McCoy (1913) noted alopecia in 47·5 per cent., cutaneous ulcers in 22 per cent., diffuse subcutaneous infiltration in 97·9 per cent., enlarged lymphatic glands in 87 per cent., and nephritis in 53·8 per cent.

Inside the cells the bacilli are said to be distributed not in cigar-like bundles like the human leprosy bacillus, but at random like pins in a packet; and, instead of displacing the nucleus, they arrange themselves round it (Marchoux 1933).

As is clear from the observations of Lampe and de Moor quoted above, the disease may often be present in a latent form.

The **bacteriology** of the disease has already been discussed in Chapter 16.

Reproduction of the Disease in Animals.—Stefansky failed to infect rats or guinea-pigs, but Dean (1905) was more successful. He inoculated 30 rats with suspensions of infiltrated skin and enlarged lymphatic glands. Many of the animals died of intercurrent disease, but 9 of them developed marked lesions. In 3 cases the

infection was passed in series from one rat to another, and from this to a third. The experimental disease ran a slow course, lasting from 6 months to a year. Post mortem, after subcutaneous inoculation, there was sometimes a local lesion containing semi-caseous material and acid-fast bacilli; in these cases the regional lymphatic glands were sometimes invaded by bacilli. After intraperitoneal inoculation the lesions were more extensive: the epiploon was infiltrated with grey masses of opaque material, which consisted of collections of cells containing bacilli. The liver was not usually involved, but in some animals there were small, pale, sharply circumscribed areas, composed chiefly of acid-fast bacilli. The capsule of the spleen was often thickened and contained bacilli, but in only one case was the organ itself involved. In 3 animals there was a tumour-like mass in the anterior mediastinum, consisting of pale-yellow material, which contained large numbers of bacilli. Small nodules in the lungs were found in two cases. The organism proved non-pathogenic to guinea-pigs, rabbits, mice, and a macaque monkey.

The way in which natural infection occurs is not known, but the presence of lesions in the skin and subcutaneous tissues suggests that it is contracted through cutaneous fissures and abrasions. According to Marchoux (1933), the disease can be reproduced by scarification of the skin; and Marchoux and Chorine (1938) state that the subcutaneous inoculation of as few as 5 bacilli will suffice to infect the rat. Wayson and Masunaga (1935), however, suggest that infection may occur through the nose. Examination of wild rats affected with leprosy, and of white rats inoculated subcutaneously, revealed the presence of acid-fast bacilli in the nasal mucosa. Moreover, nasal instillation of a lepromatous suspension was followed by development of rat leprosy. Against this suggestion is the fact that in the natural disease the bacilli seem to be commonest in the inguinal and axillary rather than in the cervical glands. The same objection applies to conjunctival infection, which Marchoux and his colleagues (1935) have shown to be successful under experimental conditions. Further observations are clearly desirable.

Sellards and Pinkerton (1938) have shown that progressive lesions can be readily reproduced by the intracerebral inoculation with rat leprosy bacilli of rats and mice, less readily of monkeys (*M. rhesus*) and rabbits, but not of guinea-pigs. In mice the infection can be reproduced serially by simple intraperitoneal inoculation.

Balfour-Jones (1937) found that the disease could be transmitted to the Syrian hamster (*Cricetus auratus*). Intraperitoneal inoculation with 0·25 ml. of a suspension of infected material from a rat caused death in about 6 months. The picture at post mortem was similar to that in rats, except that the omentum was less thickened. Lesions were commonly present in the liver and spleen, less often in the kidneys and lungs. When interstitial nephritis was observed, clumps of acid-fast bacilli were found in the interstitial tissue. In rats, it may be noted, acid-fast bacilli are never found in the kidney. Subcutaneous inoculation also produced lesions in the hamster.

JOHNE'S DISEASE

SYNONYMS.—*Enteritis chronica pseudotuberculosa bovis; Entérite spécifique chronique des bœufs; Chronischer infektiöser Darmkatarrh des Rindes;* chronic bovine pseudo-tuberculous enteritis.

Johne's disease is a specific enteritis affecting cattle, and less frequently sheep and deer, caused by an acid-fast organism known as Johne's bacillus. It was first described by Johne and Frothingham in 1895 at Dresden. They regarded it as a peculiar form of tuberculosis, possibly due to the avian type of bacillus.

The disease is fairly common in Northern Europe, and has been observed in America. It affects particularly young cows, but no age is exempt. Since, however, the incubation period is lengthy—up to about 18 months—it is uncommon to meet with the disease in cows less than 2 years old. Latent infection is apparently quite frequent. Sheep are less often attacked, though according to McEwen (1939) the disease may exact an annual toll of 5 per cent. of the animals. In this country the disease is prevalent in cattle, especially those on marshy or boggy land. Natural infection probably occurs through the ingestion of fodder that has been soiled with fæces of infected animals. It has been shown experimentally that Johne's bacillus may remain alive for several months in infected fæces and ditch water exposed to ordinary atmospheric conditions (Lovell, Levi and Francis 1944).

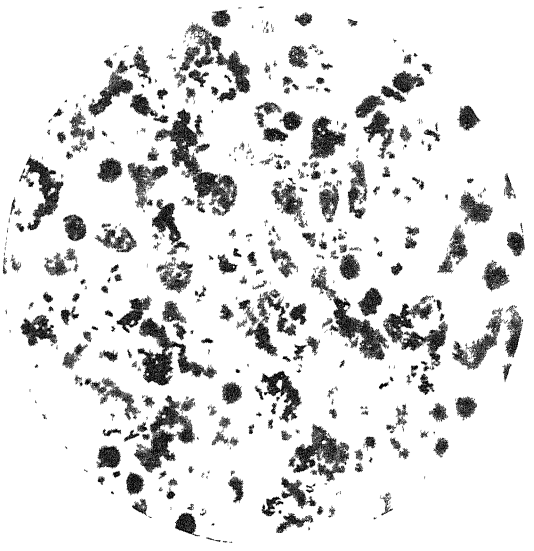

FIG. 281.

Section of intestine of cow with Johne's disease. The bacilli are seen in dense clumps, mostly intracellular (× 1000).

Clinically the disease runs a chronic course, subject often to long periods of intermission, and characterized by unthriftiness, a falling off in the milk yield, diarrhœa of varying severity, and progressive emaciation; there is no fever.

Pathologically, the main lesions are situated in the last 50 feet of the small intestine, and in the neighbourhood of the ileocæcal junction, but sometimes the whole gut is affected. The intestine is thick and rigid, looking not unlike a hose pipe; the mucosa is greatly thickened and is thrown into regular corrugations, resembling the convolutions of the cerebrum. The mucosa is smooth and pale or pink in colour, and covered with slimy material; on the surface of the corrugations it is dotted with red spots or hæmorrhages; between the folds it often has a warty appearance. Occasionally small nodules are seen, due to enlargement of solitary lymphoid follicles. There is no ulceration of the mucosa, and the peritoneal surface appears normal. The mesenteric lymph glands are usually enlarged, œdematous and pigmented. Histologically, the mucosa, and to a less extent the submucosa, are infiltrated with lymphoid and epithelioid cells, which are responsible for the thickening. Near the surface of the gut the mucosa is absolutely structureless; all traces of nuclei and cell outlines have disappeared. Giant cells are rare; there is no caseation, ulceration, fibrosis, or calcification. Short acid-fast bacilli, often in enormous numbers, are found in the mucosa lying between the glands and in the lymphoid tissue of the solitary follicles; they may invade the submucosa, and very occasionally the underlying muscle layer. The bacilli are

arranged in dense clumps, and may be intra- or extracellular. Johne and Frothingham were of the opinion that they were primarily intracellular in position, but that owing to the subsequent disintegration of the cell, they were set free in the tissue. The cellular reaction around the bacilli is diffuse, not localized as in tuberculosis. Bacilli are generally found in the mesenteric glands and sometimes in the sublingual and submaxillary glands. In sheep there may be very much less thickening and corrugation of the intestinal mucosa than in cattle. The disease can be reproduced in cattle and sheep by feeding or parenteral inoculation with pure cultures of Johne's bacillus (see Chapter 16).

The **bacteriology** of the disease has already been described in Chapter 16.

Diagnosis and Prophylaxis.—Differential diagnosis has to be made from strongylosis, coccidiosis, and particularly tuberculous enteritis. The tuberculin test with bovine tuberculin is negative, but a reaction often follows the injection of avian tuberculin (see Bang 1909, 1914). Twort and Ingram (1913) advocate the use of a preparation like tuberculin, but made from glycerine broth cultures of Johne's bacillus. M'Fadyean, Sheather and Edwards (1912) prepared a similar substance which they termed *johnin*. These products, however, do not appear to be strictly specific; reactions may be obtained in tuberculous animals. Dunkin (1928) and Minett (1933) have recorded successful results with johnin prepared by growing Johne's bacillus in a special broth medium containing dead *phlei* bacilli, and more recently (Dunkin 1933) with johnin prepared from cultures in a synthetic medium free from extracts of acid-fast bacilli. This product is said not to give rise to the non-specific swellings that sometimes follow the use of johnin made from phlei-containing media. McEwen (1939), however, found the johnin test unreliable both in sheep and cattle. His experience seems to be borne out by the results of a comparative trial conducted under the auspices of the Agricultural Research Council (Report 1941). The johnin was prepared from cultures in a synthetic medium. Two samples were used, one prepared by heat concentration, the other by precipitation. The double intradermal test was made on 103 cattle. There was considerable disagreement (*a*) between the readings of different observers, and (*b*) between the results of the skin test and the presence of Johne infection as revealed by post-mortem examination. In only 19 out of 52 reactors could infection be demonstrated at necropsy; on the other hand it was found in 6 out of 17 negative reactors. The reason for these discrepancies was not ascertained. A P.P.D. preparation of johnin, corresponding to the precipitated protein derivative of tuberculin (see p. 1328), has been described, but so far no records are available of its use in the field (McIntosh and Konst 1943).

The bacilli are sometimes found throughout the intestine; in such cases diagnosis is often possible by microscopical examination of a piece of rectal mucosa removed with forceps or a Volkmann's spoon. The bacilli are sometimes found in the fæces, generally in very small numbers (M'Fadyean *et al.* 1912); but it is impossible without cultural examination to distinguish them from saprophytic acid-fast bacilli. In any case in which acid-fast bacilli are found, it is advisable to inject them into a guinea-pig, in order to exclude the possibility of their being tubercle bacilli. Agglutination and complement fixation are said to be of little value in distinguishing Johne's bacillus from the tubercle bacillus (Twort 1912).

The disease is usually fatal, but numerous instances of apparent recovery or of long intermissions in its course are known. In some of these animals post-mortem examination has revealed the presence of intense cellular reactions in the mesenteric

glands, which had apparently resulted in the disappearance of the bacilli. It seems probable that in a proportion of animals infection remains latent and never gives rise to clinical symptoms.

Since the disease appears to be spread mainly by the contamination of water, food-stuffs and pasture land with the fæces of infected animals, preventive measures will include the destruction of diseased animals, suitable disposal of their excreta, disinfection of byres, and the ploughing-up of infected pasture. If this is impracticable, pasture land should be regarded as potentially dangerous for at least a year and should not be used for the grazing of sheep or cattle. These measures alone will not suffice to eradicate the disease. A more hopeful policy might be to test all members of the herd with johnin, to segregate and ultimately remove the reactors, to disinfect stalls and buildings, and to raise the non-infected animals on clean pastures (Hutyra and Marek 1926, Minett 1933); but until the johnin test itself can be made more reliable than it is at present, it is doubtful how far such a policy is likely to be successful.

According to Vallée, Rinjard, and Vallée (1934), subcutaneous vaccination of non-infected animals with 5–10 mgm. of living virulent cultures of Johne's bacillus affords a high degree of protection against the disease. This statement awaits confirmation.

CHAPTER 61

DIPHTHERIA AND OTHER DISEASES DUE TO CORYNEBACTERIA

THE modern conception of diphtheria as a clinical syndrome may be regarded as dating from the observations of Bretonneau in 1826. Its conception as a disease with a single bacterial cause dates from the publication of Loeffler's classical paper in 1884. Klebs had described the bacillus in the diphtheritic membrane in the previous year, but he had brought forward no convincing evidence of its ætiological rôle. The best possible introduction to a discussion of the bacteriological aspects of diphtheria is a brief summary of Loeffler's experiments. He demonstrated the presence of the bacillus, which we now know as *C. diphtheriæ*, in the throats of 13 of 22 persons suffering from clinical diphtheria. From 6 of these cases he isolated the organism in pure culture. With these strains, and with remote subcultures from them, he inoculated mice, rats, guinea-pigs, rabbits, finches, pigeons, fowls and monkeys. The mice and rats proved completely resistant. The guinea-pigs died in 2 to 5 days, after subcutaneous inoculation, showing at necropsy a localized area of hæmorrhagic œdema at the site of inoculation, pleural effusions which were often blood-stained, areas of pulmonary consolidation, and marked congestion of the suprarenals. The small birds died in every case within a few days, showing at necropsy an area of œdema, hæmorrhage and necrosis in the breast muscles, where the inoculation had been made. Many of the rabbits were inoculated into the trachea, or into the cornea ; in several of these typical false membranes developed. Similar false membranes were produced by intratracheal inoculation in pigeons. The introduction of cultures of *C. diphtheriæ* into the vagina of guinea-pigs, after minimal injury of the mucosa, was also followed in some cases by typical membrane formation, with local œdema ; and sometimes by generalized symptoms terminating in death. Attempts to produce infection without injury to surface epithelium were not, however, successful. The simple application of cultures of virulent bacilli to the mucosa of the nose or throat, or to the conjunctiva, of rabbits or guinea-pigs was without result ; nor did a monkey whose throat was vigorously brushed with a living culture develop more than a moderate inflammatory lesion which healed in a few days. Attempts to infect rabbits, guinea-pigs, fowls and pigeons by exposing them to a spray of living culture were unsuccessful. No clear case of paralysis, similar to that encountered as a sequela of human diphtheria, was observed in any of these animals. One highly significant point was noted ; in most of those animals which died the bacilli could be recovered only from the tissues in the neighbourhood of the site of infection. Cultures taken from the lesions in the internal organs or tissues usually remained sterile. Loeffler concluded that death was due not to the dissemination of bacilli throughout the body, but to the effect of some substance elaborated in the local lesion.

Thus Loeffler had shown that, in certain animals and under suitable conditions,

the bacillus which he had isolated would produce lesions closely resembling those of human diphtheria. This demonstration was the logical extension of the results recorded by Trendelenburg in 1869 and by Oertel in 1871, both of whom had succeeded in producing false membranes in rabbits and pigeons by inoculating them with material from human lesions. He had further shown that the subcutaneous or intramuscular inoculation of cultures of the bacillus into susceptible animals was followed by death associated with lesions which, while they bore little superficial resemblance to human diphtheria, were in themselves highly characteristic; that these lesions were not the direct result of tissue invasion by the bacilli: and that certain animal species were highly resistant to infection by any route.

The next important step in our knowledge of diphtheritic infection was the discovery by Roux and Yersin in 1888 that sterile filtrates from cultures of the diphtheria bacillus would kill guinea-pigs with lesions identical with those which follow the injection of the living organism. This demonstration of the presence of a potent extracellular toxin afforded an explanation of Loeffler's observation that death was not associated with any spread of bacteria beyond the local lesion. In rabbits inoculated with such filtered cultures Roux and Yersin noted the occurrence of late paralysis.

Later investigations have confirmed and extended these pioneer observations, and we now have a fairly detailed knowledge of the reaction of a large number of animal species to the diphtheria bacillus and to its toxin.

The lesions produced in experimental animals have been described on pp. 457 and 458. We are here concerned with them only in so far as they throw light on the pathogenesis of diphtheria in man. The epidemiology of diphtheria, the way in which the disease attacks herds as opposed to individuals, will be more conveniently considered in a later section of the chapter, when we have discussed the diagnostic methods on which our present knowledge largely depends.

It will be recalled that experimental diphtheritic toxæmia in the guinea-pig is associated with fatty degeneration of the heart muscle and diaphragm, and with congestion and hæmorrhage in the adrenal glands. There can be little doubt (see Bolton 1905, Dudgeon 1906, Jaffé 1920, Andrewes *et al.* 1923) that the direct action of diphtheria toxin on the heart muscle is one of the most important causes of death in human diphtheria.

With regard to the adrenal lesions, it may be noted that the gross changes, which are so characteristic of diphtheritic toxæmia in the guinea-pig, are not found in fatal cases in man. There is, however, a growing body of evidence which suggests that suprarenal congestion, with small extravasations of blood, and degenerative changes in the cortical or medullary cells, is of frequent occurrence in fatal human infections; though these lesions are revealed only by careful histological examination (Andrewes *et al.* 1923). So far as the nervous lesions are concerned we need only indicate the obvious analogy between the late paralysis of experimental diphtheria in the rabbit, guinea-pig or dog, and the characteristic paralysis in man.

We may, then, regard diphtheria as an infection in which a characteristic local lesion, the membranous inflammation of the fauces, is associated with an equally characteristic toxæmia, in which a powerful exotoxin exerts a selective poisonous action on certain groups of cells.

We have already referred to Loeffler's observation, that the diphtheria bacillus can be recovered from the local experimental lesion, but not usually from the

internal organs. These findings have been generally confirmed by subsequent investigators, though a few discordant results have been recorded (Andrewes *et al.* 1923). In human diphtheria it would appear that some degree of tissue invasion is of fairly frequent occurrence, though *C. diphtheriæ* has very rarely been isolated from the blood during life; Andrewes and his colleagues (1923) note 3 positive results in the records of 313 cases studied by Leede, Roedelius, and Reiche in Hamburg. The bacteriological findings at autopsy are somewhat discordant, and difficult to interpret. That *C. diphtheriæ* has, on occasion, been cultivated from most of the internal organs examined there is little doubt; but the technique employed has varied widely; and, with the single exception of the general agreement that the diphtheria bacillus may be isolated from the lungs in a considerable proportion of cases of fatal diphtheria, there is little agreement as to the frequency with which it may be found in the various organs and tissues. As Andrewes and his colleagues point out, the presence of *C. diphtheriæ* in the lungs may well be due to direct inhalation, rather than to active spread. The evidence, as a whole, clearly suggests that natural diphtheria in man, like experimental diphtheria in the guinea-pig, rabbit, or pigeon, is to be regarded as essentially a toxæmia, in which tissue invasion is minimal; and in which individual resistance or susceptibility to infection, and recovery or death when infected, are largely determined by the presence or rapid production of antitoxin.

This does not mean that invasiveness, as a character of the bacterium, plays no part in the natural or experimental disease. Where the *materies morbi* consists of living bacilli, some degree of local tissue invasion and bacterial proliferation must occur if a significant amount of toxin is to be elaborated and absorbed. It follows that the virulence of a particular strain of *C. diphtheriæ* is not completely defined by determining its toxigenicity.

That this is so has been demonstrated very clearly by recent observations on the case-fatality rates associated with infections caused by different types of *C. diphtheriæ*.

The Gravis, Mitis and Intermediate Types of C. diphtheriæ in Relation to Diphtheria in Man.

We have already referred (pp. 450, 462) to the description by McLeod and his colleagues (Anderson, Happold, McLeod and Thomson 1931) of three different types of *C. diphtheriæ*, and have noted that the *gravis* and *intermedius* types are associated with a high case-fatality rate, while infections caused by the *mitis* type are usually far milder.

The differences recorded are very striking. For example, the incidence of complications varies both qualitatively and quantitatively. Table 110, taken from Cooper and his colleagues (1936), makes this clear.

TABLE 110

COMPLICATIONS AND DEATHS ASSOCIATED WITH DIFFERENT TYPES OF DIPHTHERIA BACILLI.

Type.	Total Cases.	Hæmorrhagic. Per cent.	Paralytic. Per cent.	Laryngeal. Per cent.
Gravis	2,313	3·5	17·0	2·3
Intermedius . . .	1,993	3·7	9·9	1·3
Mitis	1,488	0·4	4·5	7·5

It would appear that paralytic complications are commonest in *gravis* infections, and obstructive lesions in the air passages in *mitis* infections, and that hæmorrhagic complications are far more frequent in infections due to the *gravis* or *intermedius* than to the *mitis* type. So far as albuminuria is concerned, Anderson and his colleagues (1933*a*) record a 52·6 per cent. incidence among their *gravis* cases, 52·1 per cent. among their *intermedius* cases, and 28·4 per cent. among their *mitis* cases.

There are also considerable differences in the case-fatality rate associated with the different types. McLeod (1943), who has collected data comprising about 25,000 cases from different parts of the world, gives the following figures:—

8·1 per cent. in 11,492 *gravis* cases.
7·2 „ „ „ 6,807 *intermedius* cases.
2·6 „ „ „ 6,858 *mitis* cases.

The sharp difference between the severity of the *mitis* cases and those due to infections with the *gravis* and *intermedius* types emerges clearly from the available records. It is much less clear that there is any consistent difference between the severity of *gravis* and *intermedius* infections. There is at least a suggestion (Robinson and Marshall 1934, 1935) that whichever of these two types assumes temporary dominance during a particular epidemic prevalence gives rise to the higher case-fatality rate.

All these figures, it should be noted, refer to cases treated with antitoxin. It would seem to be established that, under these conditions, the mortality associated with *mitis* infections is usually low. Variations, however, occur in different places and in different epidemics. According to Cooper and his colleagues (1936), all three types may be met with in phases of exalted and of diminished virulence, the *gravis* at its lowest corresponding to the *mitis* at its highest, and the *intermedius* at its highest surpassing the *gravis* in its lower or moderate phases of virulence.

That wide variations occur in the frequency of the different types at different times and in different places has been clearly established. Thus, Anderson, Cooper, Happold and McLeod (1933*a*) record the following frequencies in Leeds: *gravis* infections 75·62 per cent., *intermedius* infections 4·27 per cent., *mitis* infections 20·11 per cent. Later information is afforded by Cooper and his colleagues (1936) and by W. T. Russell (1943), both of whom analyse the distribution of the types in several different centres in England and Wales, and by McLeod (1943), who includes data from many different countries. In general, the predominant strain is far more often of the *gravis* or *intermedius* than of the *mitis* type, suggesting that *mitis* diphtheria is usually endemic, whereas *gravis*, and to a less extent *intermedius*, diphtheria tend to be epidemic. Changes in distribution of the different types may occur from year to year (see Robinson and Marshall 1934, Wright 1941*b*, Report 1943). For example, in Manchester the *gravis* infections rose from 23·8 per cent. in 1934 to 50·9 per cent. in 1935; in Liverpool they rose from 34·2 per cent. in 1937 to 69·6 per cent. in 1940. It may be noted that in the United States some workers have failed to type their strains satisfactorily; the reasons for this cannot be discussed here (see Perry *et al.* 1936, Frobisher 1938, 1940, 1942, Seligmann 1941).

Closely bound up with the distribution and case fatality of the different types is their capacity to give rise to clinical diphtheria in naturally Schick-negative or immunized persons. Several observations have been made on this subject. From McLeod's (1943) review it seems clear that, apart from the experience of Liverpool, where *intermedius* infections have been particularly severe, diphtheria in the immunized population has been due mainly in the past to infections with the *gravis* type. There is evidence, too, to show that in a well-immunized population diphtheria may be practically absent so long as the *mitis* type is predominant,

but that numerous cases may occur if the *gravis* type is introduced and gains the ascendancy.

The evidence at present available does not allow of any definite conclusion in regard to the factors that determine the greater virulence of *gravis* and *intermedius* as compared with *mitis* strains. Early observations (see Parish, Whatley and O'Brien 1932*a*, *b*, Anderson *et al.* 1933*a*) showed that all three types were highly toxigenic, and that the toxins appeared to be identical in respect of their neutralizability by antitoxin. Similarly no obvious differences were apparent in the virulence of the three different types for guinea-pigs. Later observations, however, have tended to reveal small but possibly significant differences between them.

Povitsky, Eisner and Jackson (1933), for example, found the minimal lethal dose of *gravis* strains for the guinea-pig to be smaller than that of *mitis* strains; they also found that antitoxin was rather more effective in controlling *mitis* than *gravis* infections. Murray (1935) reported that it was more difficult to protect rabbits with standard antitoxin against repeated doses of *gravis* bacilli than against similar doses of the other types. Gundel and König (1938) observed that, for protecting animals by active immunization against *gravis* strains a qualitatively better antigen was required than against *mitis* strains. Gundel and Erzin (1936) noticed differences in guinea-pigs infected with standard doses of the three types; those infected with *gravis* strains died soonest, and those infected with *gravis* or *intermedius* strains yielded positive cultures from the internal organs more frequently than those infected with *mitis* strains. Finally, Clauberg (1939), after examining a large number of toxins grown under standard conditions, reached the conclusion that *gravis* toxins were more potent in producing a skin reaction than *mitis* toxins and that their neutralization required more antitoxin.

This evidence, on the whole, suggests that *gravis* strains under appropriate conditions produce a slightly more potent toxin and are more invasive than *mitis* strains.

Some observers have noted a relation between the iron content of synthetic media and the potency of the toxin produced (Pappenheimer and Johnson 1936, Happold 1940); and Mueller (1941) has put forward the interesting suggestion that in the human body, where iron is abundant, *gravis* strains may be the most potent toxin producers. Zinnemann (1943), however, who grew strains of different types in a broth medium having an iron concentration similar to that in the human tissues and tested the minimal reacting dose by intracutaneous inoculation of guinea-pigs, obtained no evidence to support this suggestion.

O'Meara (1940) offers a different explanation. He finds that, if a bacteria-free saline extract of a *gravis* strain is inoculated subcutaneously into a guinea-pig along with a dose of the classical Park-Williams 8 (*mitis*) toxin, the M.L.D. of the toxin is not affected, but there is a greatly increased tissue reaction at the site of inoculation as evidenced by extensive œdema and necrosis. He postulates, therefore, the existence in *gravis* toxins of two factors, A and B, only one of which, A, is present in any considerable proportion in Park-Williams 8 toxin. This may account for the greater seriousness of *gravis* diphtheria in human beings and for the inability of commercial antiserum, which is made chiefly from Park-Williams 8 toxin, to neutralize completely both toxic factors produced by strains of the *gravis* type. No confirmation is yet available of O'Meara's work, and further observations will be required to test the truth of his explanation.

The Diagnosis of Infection in Diphtheria.

The laboratory diagnosis of infection with diphtheria depends on the demonstration of the causative organism. Though we are concerned here more with general principles than with technical details, it will be convenient to describe the current practice in most British laboratories. In the past chief reliance was placed on examination of a direct smear, and on the microscopic appearance of the growth of a Loeffler slope culture. Since the differentiation by McLeod and his colleagues (Anderson *et al.* 1931, 1933*a*, *b*) of three different colonial types of diphtheria bacilli on tellurite blood agar, and since the agreement reached by numerous workers on the advantage of using a selective medium, the study of the colonies developing on tellurite plates has assumed increasing importance in the laboratory diagnosis of diphtheria. Not only does the isolation of diphtheria bacilli in the form of single colonies carry greater assurance than their demonstration morphologically in a film containing numerous other organisms, but the recognition of their type—*gravis*, *intermedius*, or *mitis*—proves often of epidemiological and sometimes of clinical interest. We may outline the general procedure to be followed and the interpretation of the results in looking for the diphtheria bacillus in suspected cases of the disease, and in convalescents, contacts, and suspected carriers.

Suspected Cases of Clinical Diphtheria.

By examination of a smear made directly from the swab and stained preferably by the wet-film technique, it is sometimes possible to make a presumptive diagnosis of diphtheria. Though this method is advocated by a few workers, the majority of bacteriologists do not regard it with favour. It is restricted in its usefulness to throat swabs from children, and even in these the proportion of positive results in true cases of diphtheria is often fairly low. Though it should not do so, a negative result serves as an excuse to many practitioners to withhold serum for treatment. A preliminary negative report on a direct smear has frequently to be followed by a positive report on culture, thus confusing the practitioner and leading him to doubt the accuracy of the laboratory's findings. Moreover, the time taken in preparing and examining direct smears may often be spent more profitably in other ways. Without denying the value of the method in special cases, most bacteriologists are agreed that for routine work it is much better abandoned. In some laboratories a film is made from throat swabs and stained for the characteristic spirilla and fusiform bacilli of Vincent's angina. If these organisms are found microscopically in the cultural absence of diphtheria bacilli and of hæmolytic streptococci, they may afford an explanation of the clinical condition of the patient, and may be reported without prejudicing his treatment.

In the routine *cultivation* of swabs from suspected cases of diphtheria it is advisable to inoculate each swab on to a slope of Loeffler's serum, a plate of tellurite blood agar, and, for the detection of hæmolytic streptococci, on to an ordinary blood agar plate. All three cultures should be examined 18–24 hours later. Positive results obtained on both Loeffler and tellurite, or on tellurite alone, can be reported safely at once. Characteristic findings on Loeffler in the presence of a negative tellurite plate usually justify a presumptive positive report. When, however, the results are ambiguous or negative, it is better to send an interim doubtful report, and await the result of subculture or of further incubation of the tellurite plate before a final negative report is made. In cases of this sort

the finding of Vincent's spirilla and fusiform bacilli in direct film or of hæmolytic streptococci on a blood agar plate is often of value in suggesting the true nature of the infection.

This is not the place to discuss the relative merits of the various tellurite blood agar media that have been proposed. In different laboratories preference is expressed for the particular medium described by McLeod and his co-workers (Anderson *et al.* 1931), by Clauberg (1929, 1931, 1933, 1935, 1936), by Horgan and Marshall (1932), by Neill (1937), by Glass (1937), by Hoyle (1941), or by some other worker. So far, no medium can be regarded as perfect. We have given our reasons already (p. 451) for preferring a tellurite agar containing unheated and unlysed blood. Whatever medium is used, however, there will always be a small proportion of colonies that cannot be recognized with certainty within 24 hours; a final negative report should therefore not be issued for 2 days after receipt of the swab.

The combined use of a Loeffler slope and a tellurite blood agar culture enables a high proportion of all cases of diphtheria to be diagnosed bacteriologically within 18–24 hours. Early investigators, such as Weigmann and Degn (1932), Lewis (1933), Kairies (1933), Kemkes (1934), and Hasenbach (1935) found tellurite medium to give a slightly higher proportion of true positive results than Loeffler's serum. The experience of numerous workers has since confirmed their results, and has shown that in *cases* of diphtheria the causative bacillus may be demonstrated by tellurite in about 5–10 per cent. more swabs than by Loeffler. The routine use of a Loeffler slope culture has, however, numerous advantages. It shows whether the swab was suitable for examination; failure of growth suggests that the patient's throat had been treated recently with an antiseptic, or that the swab had been improperly taken or had been too long in transmission to the laboratory. Development of diphtheria bacilli is rather more rapid on Loeffler than on tellurite, and a tentative diagnosis can therefore sometimes be made earlier. Occasionally strains of diphtheria bacilli are met with that are unusually sensitive to potassium tellurite, and may not develop on primary culture in the presence of this substance; to avoid missing these, a Loeffler serum culture is a valuable safeguard. On the other hand, the presence of apparently typical diphtheria bacilli on Loeffler in the complete absence of diphtheria colonies on tellurite must always be regarded with suspicion, and a final positive report should never be sent till diphtheria bacilli have been isolated in pure culture by plating the Loeffler slope growth on to chocolate blood agar or tellurite blood agar.

The routine use of a tellurite blood agar plate is of value partly because it increases the proportion of positive results, and partly because it enables the type of the infecting organism to be determined. By careful examination of the colonial form under a binocular dissecting microscope and of the morphology of the organisms in a wet-stained film, or even by nigrosin (Fleming 1941), many workers of experience can assign correctly the majority of cultures to the *gravis*, *intermedius*, or *mitis* types; but it is always wise to confirm this preliminary identification by means of fermentation and, if necessary, virulence tests.

Shone, Tucker, Glass, and Wright (1939), who made a very careful study at Liverpool of the comparative merits of Loeffler and tellurite in the diagnosis of diphtheria cases, found that of 1,501 strains of diphtheria bacilli 92·4 per cent. were recognized on both a Loeffler slope and a tellurite blood agar plate, 2·3 per cent. on Loeffler only, and 5·3 per cent. on tellurite only. The failures of the Loeffler medium seemed to be due partly to the scantiness of the diphtheria bacilli

in some cases and the consequent difficulty of finding them among other bacteria, and partly to the atypical appearance of certain strains, especially those of the *gravis* type. The chief disadvantage of the tellurite medium lay in the slow growth of some strains of the *mitis* type. Cooper and his colleagues (1940), who made a similar series of observations in McLeod's laboratory at Leeds, found that a tellurite blood agar plate yielded at least 10 per cent. more positive results than a Loeffler slope, and led to less likelihood of missing severe cases. On Loeffler the very short form of *intermedius* type of diphtheria bacillus was found to be difficult to distinguish from unusually granular Hofmann strains. The results on Loeffler's medium at Liverpool were more favourable than those obtained in many other laboratories, probably because Wright and his colleagues had spent two years' intensive work checking the accuracy of their microscopical diagnosis. In the hands of less skilled observers the proportion of true positive results on Loeffler would have been lower, and a number of false positives would almost certainly have been recorded (see Cruickshank 1943).

Convalescents, Contacts, and Carriers.

In swabs from convalescents, contacts, and carriers diphtheria bacilli are generally fewer than in those from cases. The use of tellurite medium in their detection is not only an advantage, it is almost imperative. Numerous workers have found that approximately twice as many positive results are obtained on this medium as on Loeffler's serum. The development of the colonies is, however, often slow, and a negative report should rarely be made till the plates have been incubated for 48 hours.

Virulence Tests.

At one time the only way to ascertain whether a strain of diphtheria bacillus was virulent, and therefore potentially infective, was by inoculating it into a guinea-pig. Though this is still true if complete assurance is to be obtained, the number of virulence tests to be carried out may be greatly reduced by noting the type of diphtheria bacillus to which the strain belongs. Considerable experience now in many laboratories has shown that nearly all strains of the *gravis* and *intermedius* type are virulent, but that some strains of the *mitis* type are avirulent. Thus Parish (1936) reports 96·9 per cent., 99·5 per cent., and 99·7 per cent. of virulent cultures among large samples of *gravis* strains examined by different workers, and 94·1 per cent., 99·1 per cent., and 99·9 per cent. for *intermedius* strains, as against 80·0 per cent., 86·6 per cent., and 87·5 per cent. for strains of *mitis* type. Stallybrass (1936), quoting Wright's findings in Liverpool, reports one avirulent culture among 145 *gravis* strains, 4 avirulent cultures among 116 *intermedius* strains, but no less than 100 avirulent cultures among 231 *mitis* strains. The proportion of avirulent strains varies also with the origin of the culture. Thus strains of all three types are invariably virulent when isolated from cases of acute diphtheria. Avirulent strains are encountered among convalescents, contacts, and carriers, particularly in those with nasal and other extra-faucial infections. Strains of the *gravis* and *intermedius* type need seldom be tested for virulence unless derived from long-standing carriers. Strains of the *mitis* type from contacts, carriers, and persistently positive convalescent cases will generally require testing. The strains, however, that most require testing for virulence are atypical strains, especially those found in carriers (Cooper *et al.* 1940).

Two methods of performing a virulence test are in use—the subcutaneous and the

intracutaneous. The technique of each test varies with different workers. In the subcutaneous test it is usual to inoculate between an eighth and the whole of an 18-hour Loeffler slope culture in a 6 × $\frac{5}{8}$ in. test-tube into a guinea-pig. The importance of washing off the growth with a suitable suspending medium such as broth rather than with saline, which destroys the organisms, has been stressed by Holt and Wright (1940). These observers likewise recommend the chest as the preferential site of inoculation, since œdema is said to be more noticeable here than in the thigh. To make certain that the strain under test forms the toxin specific to the diphtheria bacillus it is wise to inoculate two guinea-pigs simultaneously, one of which is protected by means of a suitable dose of antitoxin, such as 500 units given intraperitoneally on the previous evening.

The intradermal, or Römer, method has the advantage of allowing several strains to be tested on the same animal. A Loeffler slope culture is washed off with 1 to 4 ml. of broth, depending on the amount of growth, and inoculated intradermally in a quantity of 0·2 ml. into the shaven side of an albino guinea-pig. A known virulent and a known avirulent strain should always be inoculated as controls. To protect the animal from death during the development of the characteristic skin reactions, 20 to 40 units of refined antidiphtheria serum should be injected simultaneously into the peritoneal cavity. A guinea-pig protected by the intraperitoneal injection of 500 units of serum on the previous evening should likewise be inoculated intradermally with the same strains as those used for the test animals. This precaution is desirable especially with atypical strains and with cultures of doubtful purity, so as to prevent confusion being caused by necrotic lesions due to other species of *Corynebacterium* or to staphylococci.

The Diagnosis of Susceptibility or Immunity to Diphtheria.

Modern methods of diphtheria control depend almost as much on distinguishing between the susceptible and resistant members of the human herd as on diagnosing cases and carriers. The technique that first enabled us to do this on an adequate scale was the test introduced by Schick (Michiels and Schick 1913*a*, *b*, Schick 1913). It is performed as follows.

The test toxin is stored in a relatively concentrated solution, and when required for use is diluted so that one Schick dose is contained in 0·2 ml. Part of this diluted toxin is heated to 70° C. for 5 minutes, to serve as a control. Into the flexor surface of one arm 0·2 ml. of the unheated toxin is injected intradermally, care being taken that the injection is made into the substance of the dermis in such a way as to raise a definite bulla. Into the flexor surface of the opposite arm is injected 0·2 ml. of the heated toxin. The reaction to the toxin develops at a varying rate. In some persons a positive reaction is evident after 24 hours, but in others it is not fully developed for a week. From the observations of Downie and his colleagues (Report 1942*a*), the best times to make readings would appear to be the 4th and the 7th days; if only one reading can be made, the 7th day should be selected. The following types of reaction may be observed to the toxin and the control:—

(*a*) The negative reaction—no reaction of any kind in either arm.

(*b*) The positive reaction—no reaction in the control arm.

In the test arm a circumscribed red flush appears generally after 24 to 36 hours, reaching its maximum development on the 4th to 7th day. At this time there is a circular area, 1–2 cm. in diameter, slightly raised above the general surface of the skin. This slowly fades during the following few days or more, leaving an area of brownish pigmentation, with a desquamating epidermis.

(*c*) The pseudo-reaction (negative).—This reaction, which is of the characteristic allergic type, develops equally in both arms during the first 24 hours. It is less sharply circumscribed than the true positive reaction, and fades much more rapidly. By the 4th day it has usually disappeared, leaving some slight degree of reddish or brownish discoloration.

(*d*) The combined reaction (pseudo + positive).

The control arm shows the succession of changes referred to under the pseudo + reaction. The reaction in the test arm is almost indistinguishable from that in the control arm during the first 24 hours. After this time the reaction in the test arm continues to develop, while that in the control arm commences to fade. By the 4th day the difference between the two arms is usually quite distinctive.

The positive and combined reactions are generally regarded as indicative of susceptibility. More precisely they show that antitoxin is either absent from the circulating blood or is present in only very small quantity. At one time it was thought that a positive reaction showed that there was less, and a negative reaction that there was more, than 1/30 A.U. per ml., but further experience has rendered it clear that either reaction may occur over a fairly wide range of antitoxin values (see Jensen 1931, Fraser and Halpern 1935, Leach and Pöch 1935, Parish and Wright 1938, Thelander 1940, Downie *et al.* 1941). A positive reaction may be registered with as much as 1/30 A.U. per ml. and a negative reaction with less than 1/1,000 A.U. In general, however, a positive reaction is uncommon with 1/100 A.U. per ml. or more, and rare with 1/30 A.U. or more.

The Schick test, within its limits, is a quantitative one; and the test dose must therefore be defined, and the test toxin standardized.

The Schick dose was originally defined on an empirical basis as 1/50th of the guinea-pig M.L.D.; but, as Glenny (1925) has pointed out, we are concerned in the Schick test not only with toxicity but with combining power. We want to know how much toxin the subject's tissue fluids can neutralize. The M.L.D. is not a satisfactory unit for this purpose since it is not a measure of combining power; but an adequate degree of toxicity must be ensured, since the dermal reaction depends on the presence of free toxin.

The subject was considered by the Biological Standardization Commission of the League of Nations in 1931 (see Report 1931), and two alternative definitions of the Schick dose were adopted. One reads as follows:

"The Schick test-dose, for injection in a volume of 0·2 ml., shall be that quantity of toxin which, when mixed with 1/750th part or more of an international unit of antitoxin and injected intracutaneously into a normal guinea-pig, causes no local reaction; but, when mixed with 1/1,250th part or less of an international unit and similarly injected, causes a marked reaction of the type of a 'positive' Schick reaction; *provided that* the toxin is such that 1/25th of the Schick test-dose as above determined, without admixture with antitoxin, when injected intracutaneously into a normal guinea-pig, causes a definite local reaction of the type of a 'positive' Schick reaction; but that 1/50th of the Schick test-dose, similarly injected without admixture, causes no local reaction of this type."

In the alternative definition the main clause defines the Schick dose in terms of the M.R.D., and the proviso deals with combining power. Both conditions must be fulfilled under the Regulations (1931) made in Great Britain in accord with the Therapeutic Substances Act (1925).

As a possible alternative to the Schick test, the actual amount of circulating antitoxin in a person's blood may be determined by titration, using the Römer technique. This is clearly a more accurate method, and entails a single withdrawal of blood compared with the intradermal injections and their observation during the following few days. The necessary animal inoculations might be supposed to prevent the adoption of this method as a routine. Jensen (1933*b*), however, who uses rabbits instead of guinea-pigs for the intracutaneous injections, thus increasing the number of tests that can be carried out on a single animal, considers it the method of choice for both convenience and accuracy.

The evidence now available leaves no reasonable doubt that a person who reacts negatively to the Schick test, or who has been shown to possess an equivalent

amount of circulating antitoxin is comparatively immune to all ordinary risks of infection. This evidence has in part been obtained by keeping under observation samples of the general population whose Schick reaction has been determined, in part by observing the behaviour of negative and positive reactors when exposed to high risks of infection. The evidence available under the latter head is more impressive, and more readily obtained, than that under the former, for the simple reason that, where the risk of infection and consequently the incidence of disease are high, the observation of relatively small samples over relatively short periods of time will serve to reveal statistically significant differences, if such exist. This problem will be referred to again in discussing the efficacy of active immunization. It must be made clear, however, that the degree of immunity possessed by Schick-negative reactors is far from absolute, and that, in fact, quite large numbers of cases of diphtheria have been reported in immunized persons many of whom were probably Schick-negative. Such cases are usually due to infection with the *gravis* type of diphtheria bacillus (Cooper *et al.* 1936, McLeod 1943) and seldom prove fatal.

We may note here the single instance of a direct experiment on man which has, so far as we are aware, been placed on record. Guthrie, Marshall and Moss (1921) collected eight volunteers and determined their reaction to the Schick test; four reacted positively, two negatively, and two gave pseudo-reactions which were read as negative. The throat of each of these eight volunteers was swabbed with a virulent culture of *C. diphtheriæ*. The organism established itself on the tonsils of the four positive reactors, and of three of the four negative reactors. The four positive reactors developed clinical diphtheria; the three negative reactors became temporary carriers without showing any sign of the disease.

In discussing the nature and origin of the normal antibodies in Chapter 49, we have already described the observations of Zingher and of others on the results obtained in the application of the Schick test to large samples of the normal population, and have considered the opposing theories of the origin of normal antitoxin as the result of latent infection, or as a phase of normal biochemical ontogeny, in the absence of any specific stimulus; and we have expressed our personal view that it is impossible to account for the observed distribution of natural antitoxic immunity among the population in general, and among certain isolated groups in particular, without assuming that natural immunization plays a highly important rôle.

The Treatment of Diphtheria with Antitoxin.

The nature of antitoxic immunity and the general principles that determine its practical application have been discussed in Chapter 46. We are here concerned with the methods that are employed in the particular case of diphtheria in man, and the available data with regard to their efficacy.

As regards the commercial preparation of antitoxic sera, we need only note that the animal almost universally employed is the horse, and that immunization is usually carried out by the administration of increasing doses of toxic filtrates, administered at intervals of a few days. The initial dose must be minute, 0·01 ml. or thereabouts. The final dose, usually reached within a period of 6 weeks to 2 months, may be very large, 1 litre or more. When a satisfactory titre has been attained the horse is bled from the jugular vein, with strict precautions as regards sterility; the serum, after separation from the clot, is filtered through a coarse

porcelain candle, and 0·3 to 0·5 per cent. tricresol is usually added as a further precaution to maintain sterility (Dean 1908). The average serum so obtained contains between 600 and 800 units of antitoxin per ml.

Apart from its great theoretical interest, the isolation of antitoxin in a state of chemical purity would be an important advance from the practical point of view. This has not yet been achieved, but considerable success has been attained in the concentration of the active constituents (Brieger and Ehrlich 1893, Brieger and Cohn 1893, Brieger and Boer 1896, Pick 1902, Gibson 1905, Banzhaf and Gibson 1907, 1908–9, Banzhaf 1912–13, Andrewes *et al.* 1923). The methods employed, which vary in minor points of technique, depend on the demonstration that the major part of the antitoxin is contained in that fraction of the serum globulin which is precipitated by half saturation with ammonium sulphate, but redissolved when the precipitate is extracted with a saturated solution of sodium chloride. This so-called "pseudoglobulin" fraction can be separated from the euglobulin, and from the serum albumin. The process is accompanied by the loss of an appreciable fraction of the antitoxin originally present in the serum; but the concentration of antitoxin in the finished product may be increased six or eight times as compared with the untreated serum; and there is a relative elimination of non-effective protein material, though the protein content per ml. is appreciably increased during the process of concentration. An even greater degree of purification is now achieved by the use of proteolytic enzymes to digest much of the unwanted protein (Pope 1938, 1939). The resulting *refined diphtheria antitoxin*, as it is called, has been found by Glenny and Llewellyn-Jones (1938) to be absorbed more rapidly and eliminated more slowly in guinea-pigs than the so-called concentrated diphtheria antitoxin, which is the product of precipitation with ammonium sulphate. It has, moreover, the great advantage of giving rise to serum sickness in a much smaller proportion of patients than either crude or concentrated antiserum; probably not more than about 10 per cent. of diphtheria patients develop symptoms after its use, and these are usually mild.

Our object in treatment will obviously be to introduce as much antitoxin as we can, at the earliest possible moment, since we must act on the assumption that the beneficial result of our interference will probably be limited to the neutralization of the toxin which has not yet been firmly anchored to the cells which are susceptible to its action.

In support of this view we may cite such experimental results as those recorded by Glenny and Hopkins (see p. 1031). For the same reason we should give therapeutic injections of antitoxin intravenously, intraperitoneally or intramuscularly, never subcutaneously, since the relatively slow absorption from the subcutaneous tissues will defeat our main objective (see p. 1124).

It is sometimes taught that the administration of antitoxin is without effect after the 5th or 6th day of disease, a dictum based mainly on the figures recorded by Faber (1904), which show a progressive increase in case mortality from 7·1 per cent. in patients receiving antitoxin on the first day of disease, to 17.0 per cent., 21·3 per cent. and 19·9 per cent. among those treated on the 6th, 7th and later days respectively. It has, however, been pointed out that such hospital statistics are of little value, because there is an important element of selection of which they take no account. Cases admitted to hospital on the 5th day or after will, *ipso facto*, include a large number of severe infections; since the delay in admission will in most cases be due either to delayed diagnosis, often resulting from failure to obtain a medical opinion, or to an unwillingness to resort to hospital. In either case those patients who are well on the way to recovery by the 5th or 6th day will never be admitted, while those who are seriously ill will be transferred to hospital, either because a late diagnosis has been arrived at, or because the serious condition of the patient has alarmed his friends.

There is no justification for withholding antitoxin because a case is in an advanced stage, though every effort should be made to ensure that it is given early in the disease.

A system of dosage in common use is that advocated by Park (1921) (see Table 111); but there has been a tendency to increase the amount of antitoxin given in the severer type of case as the result of the experience of recent years, and this tendency seems likely to continue. Thus, Bie (1922), in an admirable review of the evidence in regard to the value of antitoxin treatment in diphtheria, advocates the administration of very large total doses (92,000—170,000 units). Harries (1945) likewise recommends a large single dose, but considers that it should rarely be necessary to give more than 50,000 units, provided part or whole of the dose is given intravenously.

TABLE 111

UNITS OF ANTITOXIN TO BE ADMINISTERED TO CASES OF VARYING GRADES OF SEVERITY. (After Park.)

Age or Weight of Patient.	Mild Cases.	Early Moderate.	Late Moderate and Early Severe.	Severe and Malignant.
Under 2 years. 10–30 lbs. wt.	2,000–3,000	3,000–5,000	5,000–10,000	7,500–10,000
2–15 years. 30–90 lbs. wt.	3,000–4,000	4,000–10,000	10,000–15,000	10,000–20,000
Adults. 90 lbs. or over .	3,000–5,000	5,000–10,000	10,000–20,000	20,000–50,000
Route of administration .	Intramuscular	Intravenous	Intravenous	Intravenous

It might be expected that after some 50 years it would be easy to produce irrefutable statistical evidence of the beneficial effects of the antitoxin treatment of diphtheria in man. The evidence does, in truth, seem decisive to most of us; that it is still possible to bring forward contrary arguments that are not altogether specious is due to the fact that once a strong presumptive case has been made out in favour of a particular therapeutic measure it is not justifiable to continue the period of trial at a risk of human lives.

Of the classical studies from the early days of antitoxin treatment, the only one that affords an entirely satisfactory basis for comparison is that of Fibiger (1898). For a period of one year all cases of diphtheria admitted to hospital were divided into two groups by separating those admitted on alternate days. All cases admitted on one day were given antitoxin, all those admitted on the next day were treated without antitoxin, and so on throughout the period of trial. The results were as follows: of 239 cases treated with antitoxin 8 died, a mortality of 3·5 per cent.; of 245 cases treated without antitoxin 30 died, a mortality of 12·25 per cent. Applying the formula given on p. 987, the difference between the case mortality in the two groups is 8·75 per cent. and the standard error of this difference is 2·445 per cent., so that the odds against the difference being due to random sampling are several thousands to one (see Table 60, p. 985).

Other results recorded during the early and middle 'nineties—comparisons between the case-fatality rates in hospitals in which antitoxin was given and others in which it was not, or between the experience in one hospital before and after the introduction of antitoxin—all pointed in the same direction; and the period of trial ended with the adoption of antitoxin as a routine method of treatment.

If we survey the course of events since that time we find that they strongly support the view that the use of antitoxin has resulted in a significant lowering of

the case-fatality rate; but they would hardly be accepted as demonstrative proof in the absence of the earlier and controlled trials.

There is, for instance, the decline in the case-fatality rate as shown by the returns of the hospitals of the Metropolitan Asylums Board (see Table 112).

TABLE 112

Year.	Case Mortality per cent.	Year.	Case Mortality per cent.
1889	40·7	1909	9·4
1890	33·5	1910	7·8
1891	30·6	1911	8·4
1892	29·3	1912	6·2
1893	30·4	1913	6·2
1894	29·3	1914	7·9
1895	22·8	1915	8·4
1896	21·2	1916	6·8
1897	17·7	1917	6·7
1898	15·4	1918	7·7
1899	13·9	1919	9·3
1900	12·3	1920	8·6
1901	11·1	1921	8·8
1902	11·0	1922	8·7
1903	9·7	1923	6·8
1904	10·0	1924	7·0
1905	8·3	1925	5·0
1906	8·8	1926	4·9
1907	9·6	1927	4·0
1908	9·7		

Antitoxin came into general use about 1895, and the figures suggest that it had produced its full effect on the case-fatality rate about 10 years later; since when this rate has been kept down to a figure of about one-third of that prevailing in pre-antitoxin days. But, if we are disposed to be critical, we shall note that the downward trend had shown itself before the introduction of the antitoxin, and that secular trends in case fatality are known to occur apart altogether from the introduction of new therapeutic measures—as in the classical example of scarlet fever.

There is another factor which would add to our doubt. At about the same time as antitoxin was coming into general use the basis of diagnosis of diphtheria was changing. The introduction of bacteriological methods made it possible to recognize as diphtheria many cases that would earlier have been regarded as non-diphtheritic anginas. For this reason the total of recorded cases would tend to be increased by the inclusion of many mild infections, and the recorded case mortality would automatically fall.

Somewhat better evidence is afforded by the figures for the mortality rates in cases of laryngeal diphtheria, excluding those cases treated by tracheotomy. This gives a series of cases in which the clinical signs were alone sufficient to establish a diagnosis, and in which the infection may be regarded as uniformly serious. In 1894 the mortality in this class of case, in the M.A.B. hospitals, was 62 per cent.; after 1895 it fell, at first rapidly, then less steeply, until in 1910 it was 11·7 per cent. (Andrewes *et al.* 1923). Even here, however, the possible intrusion of other factors, such as changes in the proportion of all laryngeal cases treated by tracheo-

tomy, and in the period at which tracheotomy is performed, make it difficult to assess the real significance of the recorded figures.

In any case, the clear historical evidence of long-period fluctuations in the severity of diphtheria, as of other infective diseases, forbids us to place too great an emphasis on a progressive fall in mortality lasting for a few decades; and, in recent years, there have been signs that the disease is still able to reassert its killing power. Deicher and Agulnik (1927), for instance, give figures for a Berlin hospital and for one of the districts of that city (see Table 113).

TABLE 113

Rudolf Virchow Hospital.

Total cases	132	140	114	172
Deaths	8	7	10	30
Mortality per cent.	6·1	5·0	8·7	17·4
Alt Berlin.				
Year	1923	1924	1925	1926
Total cases	1,068	1,016	1,109	1,421
Mortality per cent.	7·58	5·9	8·1	11·1

It is tempting to suggest that this change has been caused by an increase in the proportion of cases due to the *gravis* or *intermedius* types. During the period 1930–32, for instance, a severe form of diphtheria was prevalent in Leeds. It was during this epidemic that McLeod and his colleagues differentiated the three types, and we have already noted that the *gravis* cases showed a case mortality of 13·1 per cent., while no deaths occurred among the *mitis* infections. The case-mortality rate for all infections in this series of cases, *gravis*, *intermedius* and *mitis* combined, was 10·3 per cent., a figure that may be compared with those given in Table 112. Similar figures have been quoted from other observers. It is very possible that this explanation is the true one; but, since we have no information with regard to the relative proportion of *gravis*, *intermedius* and *mitis* infections during the earlier years of this century, when the prevailing case mortality of diphtheria was low, we must wait for further experience before granting it definite acceptance.

We are thus left with a mass of statistical data all of which is compatible with the view that the use of antitoxin has had a considerable effect in lowering the mortality from diphtheria, but most of which is indecisive. Taking the general trend of this evidence with Fibiger's early observations and adding to it the decisive results obtained in animal experiments, we have a sound basis for the conclusion that antitoxin provides the best available method of treatment, and that its early administration is the essential factor in controlling the clinical disease. The failure to establish a statistical case that is beyond criticism merely shows how hard it is to assess the real effect of any remedy in any human disease, unless that effect is so dramatic as to be immediately and consistently evident.

In view of recent experience, in Germany, in England and elsewhere, there is, however, an obvious need to re-examine the problem with a view to improving, or adding to, our present therapeutic reagents.

The Standardization of Diphtheria Antitoxin.

We have already referred to the standardization of diphtheria antitoxin, in our discussion of the toxin-antitoxin reaction (pp. 238–239). We noted that the instability of a toxic filtrate renders it quite unsuitable as a standard of reference, and that, for this reason among others, Ehrlich's original definition of the unit of antitoxin (A.U.) as *the smallest amount of antitoxin that will neutralize 100 M.L.D. of toxin*, using the guinea-pig as the test animal, had soon to be abandoned, and has been replaced by a unit defined in terms of a standard antitoxin. Such a standard antitoxic serum, when dried and preserved *in vacuo* in the presence of phosphorus pentoxide, maintains its potency over long periods of time. It has, moreover, become a general principle in biological standardization that a reagent shall, wherever possible, be assayed by comparing its potency with that of a standard preparation of the same reagent, to which some unit value has been assigned by international agreement. In the case of diphtheria, Ehrlich's original antitoxin was adopted as the international standard. The correct definition of a unit of diphtheria antitoxin is as follows.

One unit of diphtheria antitoxin (1 *A.U.*) *is contained in that amount of an antitoxic serum that has the same total combining capacity, for toxin and toxoid, as one unit of the standard antitoxin.*

Standard antitoxin is now preserved and issued by selected Institutes, and is tested from time to time under the auspices of the Biological Standardization Commission of the League of Nations (see Report 1923).

The methods employed in measuring the potency of an antitoxic serum, and the knowledge that has been acquired in their development and use, have played so large a part in the evolution of our present methods of controlling the disease that, at the cost of some repetition, it is desirable to summarize them here. Three such methods are available. Two of them depend on *in vivo* tests, the third on an *in vitro* titration.

The first is Ehrlich's classical method of injecting mixtures of toxin and antitoxin subcutaneously into guinea-pigs; and this method is still the official one in many countries (see Report 1923, Prausnitz 1929). It has been found convenient to employ the end-point of toxæmic death rather than the end-point of complete neutralization—the L— rather than the Lo dose of toxin (see p. 239). The first procedure is, then, to determine the smallest amount of a suitable toxic filtrate that, when mixed with one unit of standard antitoxin and injected into a 250 gm. guinea-pig, will, on the average, kill the animal by the 4th day. In practice batches of guinea-pigs are injected with each mixture prepared and the mixture producing a 50 per cent. mortality, or thereabouts, is regarded as containing the L+ dose of toxin. The procedure is then reversed. The amount of toxin is held constant at the L+ dose, and the amount of the serum to be tested is varied, again using an adequate number of guinea-pigs for each dose in the range within which the L+ mixture is expected to fall. The amount of serum in the mixture that gives a 50 per cent. mortality within 4 days contains one unit of antitoxin. The number of guinea-pigs that must be inoculated with any such mixture in order to give an estimate of the unit value of an antitoxic serum within a specified margin of error depends on the factors considered in Chapter 43. In practice a rough preliminary titration is made, and the exact value of the serum is then assessed using larger numbers of guinea-pigs.

The second method depends upon the observation of Römer (1909) that the intradermal injection into a guinea-pig of 1/250–1/500 M.L.D. of toxin is followed by a localized swelling and erythema. With slightly larger doses, this erythematous reaction is followed by definite necrosis. The neutralization of toxin by antitoxin prevents this reaction.

The great advantage of this method is that it allows the toxicity of several different mixtures to be tested on a single guinea-pig, and thus not only economizes animals but eliminates much of the difficulty due to differences in susceptibility between one guinea-pig and another. The successive steps in the process of standardization do not differ in any essential from those followed in the Ehrlich method. Varying amounts of a suitable toxin are first mixed with one unit of the standard antitoxin and 0·2 ml. of each mixture is injected into the depilated skin of a guinea-pig. The amount of toxin in the mixture that gives a minimal skin reaction is noted. This amount of toxin has been defined by Glenny and Allen (1921) as the Lr dose. A series of mixtures is now prepared in which the Lr dose of toxin is mixed with varying amounts of the serum under test, and 0·2 ml. of each of these mixtures is injected intradermally into another guinea-pig. The amount of serum in that mixture that gives a minimal skin reaction contains one unit of antitoxin. In practice it is customary to use fractions of 1.A.U. and corresponding fractions of the Lr dose of toxin, in order to avoid the administration of lethal doses of toxin in the mixtures containing toxin in excess.

The third method depends on the observation of Ramon (1922) that a satisfactory measure of the combining power of an antitoxic serum can be obtained by mixing falling amounts of the serum with a constant amount of toxin and noting the ratio of one reagent to the other in the tube that first shows flocculation. This is the method of optimal proportions (see p. 202). Glenny and Okell (1924) (see also Glenny and Wallace 1925) have suggested that the amount of toxin corresponding to one unit of antitoxin in the mixture that shows optimal flocculation when tested by the Ramon method should be called the Lf dose. The procedure with this *in vitro* test is essentially the same as with either of the *in vivo* methods. The Lf dose of a suitable toxic filtrate is determined by titration against the standard antitoxin. The amount of the serum under test that gives optimal flocculation with the Lf dose of toxin is determined by a second titration. This amount of serum contains one unit of antitoxin.

Table 114 (see Glenny 1925) sets out the units (or named doses) employed in testing diphtheria toxin and antitoxin. The meaning to be attached to the Schick dose has been considered on p. 1377.

TABLE 114
(After Glenny 1925.)

Character measured.	Unit or Dose.		Result of Inoculation in Guinea-pig.
	Toxin.	Antitoxin.	
Toxicity . . .	M.L.D.	—	Death on 4th day.
„ . . .	M.R.D.	—	Minimal skin reaction.
Combining power	L+ dose	1 A.U.	Mixture causes death on 4th day.
„ „	Lo „	1 A.U.	Mixture causes minimal œdema.
„ „	Lr „	1 A.U.	Mixture causes minimal skin reaction.
„ „	Lf „	1 A.U.	Mixture gives optimal proportions for flocculation.
„ „	Schick „	0·001 A.U.	

The comparison of large numbers of different antitoxic sera—natural or concentrated—by these different methods has brought to light facts of considerable theoretical and practical importance. The L+ dose of toxin is always appreciably larger than the Lo dose. The Lr dose of toxin always approximates closely to the Lo dose, as would be expected, since a very small excess of unneutralized toxin will elicit the Römer reaction. The Lf dose is, in general, slightly less than the Lr dose. Glenny (1925) notes the following relation between the various doses of an average toxic filtrate: L+ dose = 0·21 ml., Lo dose = 0·18 ml., Lr dose = 0·175 ml., Lf dose = 0·155 ml. The ratio of the Lf

dose to any of the *in vivo* doses is not constant for all toxic filtrates. Antitoxin gives flocculation with both toxin and toxoid while the determination of the L+, Lo and Lr doses depends on the presence of unneutralized toxin, and is hence affected by differences in the proportion of toxin to toxoid. Moreover, as was shown by Glenny, Pope and Waddington (1925), not only does the Lf/Lr ratio vary from one toxic filtrate to another, when these are tested against the same serum, but the Lf/Lr ratio of a single toxic filtrate varies when it is tested against different antitoxic sera. It follows that, when sera are compared with one another by *in vivo* and *in vitro* methods, their apparent relative potency may vary according to the method of comparison employed: and, with such sera, the ratio $\frac{\textit{in vitro}\text{ value}}{\textit{in vivo}\text{ value}}$ will vary from one serum to another. Glenny and his colleagues note that they have obtained *in vitro*/*in vivo* ratios varying from 0·4 to 2·0 with different antitoxic sera, and that, in general, if the Ehrlich value is considerably higher than the Ramon value *i.e.* if the *in vitro*/*in vivo* ratio is low, the serum will be found to give rapid flocculation; while, if the Ramon value is higher than the Ehrlich value, the serum will be found to give very slow flocculation and the toxin-antitoxin complex will show considerable dissociation on simple dilution. In their later papers, Glenny and his colleagues use the inverse ratio—*in vivo*/*in vitro*—so that a serum with a ratio greater than unity has a greater protective action than its flocculation value would lead one to expect.

Such findings as these clearly raise the question as to whether the protective action of an antitoxic serum is determined solely by its antitoxic content, as measured by one or other of the methods commonly employed. This question has been discussed on p. 1030, where it was noted that antitoxic sera may differ in *avidity*, as well as in their total capacity for neutralizing toxin. It was noted also that this avidity appears to be determined by the firmness of the toxin-antitoxin union, and that avid sera (those that unite firmly with toxin) are more effective than non-avid sera, those that form a loose union with toxin.

The avidity of antitoxic sera appears to be determined, at least in part, by the type of serum protein with which the antitoxin is associated. Thus (Barr and Glenny 1931*a*, *b*, Glenny and Barr 1932, Glenny *et al.* 1932) if successive globulin fractions are precipitated with increasing amounts of ammonium sulphate, the earlier fractions show a higher *in vivo*/*in vitro* ratio, a higher dilution ratio and a greater curative power in rabbits than the original serum, while the avidity as judged by these tests decreases with each successive fraction precipitated.

Non-avid sera do not form a high proportion of the antidiphtheria sera obtained in routine serum production, and Glenny and his colleagues note that they are usually derived from horses that have proved difficult to immunize. With other antitoxic sera (see Glenny *et al.* 1932) it would seem that they may occur more frequently.

Interesting light has been thrown on these findings by the more recent observations of Kekwick and his colleagues (Kekwick and Record 1940, Kekwick *et al.* 1941). They find that, of the three globulin fractions separable by the electrophoretic method from diphtheria antitoxic horse serum, the α component has no detectable antitoxic activity. The antitoxic β and γ components, which together account for the total activity of the serum, differ from each other in several respects, notably in their flocculation time, the composition of their floccules, and their *in vivo*/*in vitro* ratio. The γ component flocculates more rapidly in the presence of toxin, and has therefore a higher *in vivo*/*in vitro* ratio; the floccules formed contain twice as much antitoxin nitrogen as those formed by the β globulin. In the horse's serum the γ component appears earlier during the course of immunization than the β, which, however, continues to increase as further injections of toxoid are given. The γ antitoxin precipitates at lower salt concentrations than the β antitoxin, and tends therefore, during the ordinary concentration process, to be salted out with the euglobulin fraction and discarded, so that the bulk of the antitoxin remaining in the pseudoglobulin fraction is of the β type. The proteolytic method used in the preparation of refined serum also favours the retention of the β at the expense of the γ antitoxin.

It is apparent that the proportion of the β and γ components in different batches of therapeutic serum is subject to variation. The suggestion is that the avidity of the serum is determined to some extent by the proportion of γ globulin, and that batches of sera high in this respect are likely to be of greater therapeutic efficacy than others containing mainly β globulin. Such an explanation is not inconsistent with McSweeney's (1941) observations on the successful results obtained with a particular serum in the treatment of cases of hypertoxic diphtheria (see also Trevan 1941).

These findings do not, of course, lessen the importance of determining the antitoxin content of a serum in terms of standard units, or of producing sera with the highest possible antitoxin content. We clearly want to know how many units we are giving, and to give as many units as we can. They do suggest that the protective or curative value of a serum is not always completely described by stating the number of units it contains; and it may prove desirable in the future to adopt some standard of avidity in addition to our standard of content.

The Treatment of Carriers.

Thomson, Mann, and Marriner (1928–29) found that a high proportion of pure throat carriers became negative after tonsillectomy. Valuable as this method is, it is limited in its application to throat carriers, who constitute only about 10 per cent. of the total. Up till recently little could be done to free the nasal carrier, but the introduction by Delafield, Straker and Topley (1941) of sulphonamide snuff has revolutionized the treatment of these patients. The inhalation of 33 per cent. sulphathiazole in 67 per cent. magnesium carbonate about 6 times a day cures the great majority of nasal carriers within a fortnight. If an associated hæmolytic streptococcal infection is present it may be advisable to use pure sulphanilamide snuff, as recommended by Boissard and Fry (1942).

The Epidemiology of Diphtheria.

Before discussing the prophylaxis of diphtheria it is necessary to have in our minds a picture of how the disease behaves under natural conditions. This picture, as it has been presented to us by the combined studies of bacteriologists and epidemiologists, using the Schick test and the throat swab, is far more detailed and informative than the corresponding picture that we possess for other diseases. For this reason it was selected as an illustrative example in our general discussion of herd infection and herd immunity in Chapter 56, and reference should be made to that chapter. We may add here a few additional particulars with regard to the natural history of the disease, that were not relevant to the more general discussion.

Diphtheria is a disease which shows a characteristic age incidence. Greenwood (see Andrewes *et al.* 1923) has calculated the probability of being attacked by diphtheria at different ages for three samples of the population, in different places and at different times. The figures selected were those for Breslau (1886–90), Manchester (1911–12), and London (1910–12). In the case of London the rates for males and females were calculated separately. In Breslau the peak of the curve falls in the age group 2–3, with a slight decline in the group 3–4. In Manchester the maximum is at 3–4, with a slight decline at 4–5. In London the maximum for both sexes is at ages 4–5. All four curves are definitely skew, the mode falling well to the left. Diphtheria is rare during the first year of life, and then becomes increasingly frequent until the maximum frequency is reached somewhere between the 2nd and 5th year. The incidence declines slowly until the age group 5–10, then rapidly during the age group 10–15, after which the probability of contracting diphtheria is small. It becomes still smaller in the age

group 15–20, and remains at a very low level during the rest of life. These figures, it must be realized, refer to the behaviour of diphtheria before the introduction of artificial immunization. The distribution of clinical cases of disease in a population a considerable proportion of which has received prophylactic inoculation is usually very different, and is determined largely by the age and sex of the unprotected members of the community.

Apart from this variation in susceptibility at different ages, diphtheria shows a curious capriciousness in its incidence among small communities containing many members of susceptible age. The attack rate among those exposed to risk may be very low, and varies very widely from one outbreak to another.

Diphtheria is not markedly associated with density of population, if we measure that elusive variable by computing the total population within some unit area; indeed, over considerable periods in its history, the disease has shown a marked predilection for rural as opposed to urban conditions. It is, however, typically a disease of schools, and of institutions where children are herded together at susceptible ages. Moreover, a particular school or institution may form an endemic centre of the disease for a period of months or years.

Under conditions in which the majority of cases of clinical diphtheria are removed to an isolation hospital, it is probable that the spread of the disease is due mainly to the occurrence of carriers (see Savage 1909, Doull and Lara 1925). We have previously given figures for the frequency of carriers of *C. diphtheriæ* among various classes of contact, and among the population at large. The carrier state is by no means confined to those who have themselves passed through an attack of disease; but, since the diagnosis of clinical diphtheria at once brings a patient under observation, and involves some degree of control and a considerable degree of responsibility on the part of the medical authorities, it is of interest to note the rate at which the proportion of carriers decreases during and after convalescence.

An investigation carried out by Hartley and Martin (1919–20) has yielded valuable information on this point. The study was made on 457 young adults suffering from faucial diphtheria. A swab was taken on the day of admission, and every 7th day thereafter, till three successive negative results were obtained. The time at which any individual ceased to carry *C. diphtheriæ* was calculated as being half-way between the last positive and the first of three successive negative swabs. The data were complete for the first 50 days, after which some of the patients were no longer under observation. The results were plotted in the ordinary way, using either the numbers still carrying, or the logarithms of those numbers, as ordinates, and time as abscissæ. It was found that the latter curve after the first five days from admission, gave a close approximation to a straight line. The general form of the equation of such a curve is $\frac{\log n_1 - \log n_2}{t_2 - t_1} = \mathrm{K}$, where n_1 and n_2 are the numbers carrying at times t_1 and t_2. If we take time as measured from the fifth day after admission, this may be expressed in the form

$$\log n = \log n' - \mathrm{K}t,$$

where n is the number carrying on any given day, n' is the number carrying on the 5th day, and t is the time interval in days measured from the fifth. The equation to the curve which gave the best fit was calculated by Greenwood as

$$\log n = 2{\cdot}6002 - 0{\cdot}0218\, t.$$

The observed and calculated number of carriers for the first 50 days were as given in Table 115.

TABLE 115

Days after Admission.	Number carrying (observed).	Number carrying (calculated).
5	392	—
10	302	310
15	232	242
20	194	189
25	156	147
30	118	115
35	92	89
40	70	70
45	52	54
50	41	42

The agreement is obviously very close, and such a relationship between lapse of time and the disappearance of bacilli suggests that this disappearance is due to the operation of a large number of small causes acting independently, in other words to chance. It would seem that a person who has carried *C. diphtheriæ* for 6 weeks or more is, on the average, just as likely to become free during the next few days as another who has carried for only a week. There are, however, as Hartley and Martin point out, a few persons with obviously unhealthy tonsils who carry persistently, but cease to carry after tonsillectomy.

It may be noted that the constant 0·0218 in the formula quoted above indicates that about 5 per cent. of those carrying on any one day have ceased to carry on the day following. In order to determine whether this rate of clearing held true in general, or applied only to this particular sample, data collected from various published reports were analysed in the same way. It was found that the general form of the curve was very similar in each case, *i.e.* the logarithmic relation between carrier rate and time held good, but the value of the constant varied very widely, such figures as 0·018, 0·093, and 0·202 being obtained. Some adjustment is necessary because, in certain of these series, the test of clearance was a single negative swab, but the value of the constant in Hartley and Martin's series would only be altered to 0·032 on this basis, so that the rate of clearing under different conditions varies considerably, a fact which seems to merit further investigation.

A larger and equally illuminating series of figures recording the apparent rate of disappearance of diphtheria bacilli in convalescents at the North-Eastern Hospital has been published by Thomson, Mann and Marriner (1928–29). Nose and throat swabs from proved cases of diphtheria were taken once during the 2nd and once during the 3rd week, and after that twice a week till six consecutive negative cultures had been obtained. Cases in which the bacilli persisted for over 12 weeks from the beginning of the illness were regarded as carriers. Of 3,208 cases investigated, 242, or 7·5 per cent., became carriers. Table 116 shows the proportion of cases, exclusive of carriers, that became negative in successive weeks.

It will be seen that infection disappeared from the throat much quicker than from the nose. Analysis of these figures showed that when the throat only was affected the rate of clearance was practically the same at all ages, but that when the nose or nose and throat were affected the rate of clearance was slower in younger than in older patients. Of 285 carriers on which information is afforded, including the 242 already mentioned, 255, or 89·5 per cent., were infected in the nose or nose and throat, 26 in the throat only, and 4 in the ear only. The average time spent in hospital was roughly 7 months, and the longest 21 months. The age distribution of the total cases is not given, but it is mentioned that 55·7 per cent. of the carriers were under 7 years of age and only 4·5 per cent. over 13 years of age.

Wright (1941*a*), who records his experience at Liverpool on the rate of disappearance of diphtheria bacilli from the nose or throat of 311 convalescent patients, obtained results similar to those recorded by Hartley and Martin (1919–20). He made the interesting observation that clearance was most rapid in patients infected with the *intermedius*, and slowest in those infected with the *gravis* type. Examining swabs taken at weekly intervals and inoculated on to tellurite blood agar slopes, he found that a negative result was often followed by a positive, and that in 2·5 per cent. of patients three successive negatives were followed by a positive. The customary demand for three consecutive negative results does not therefore ensure freedom of the patient from infection on discharge. The unfavourable effect of an associated hæmolytic streptococcal infection on the persistence of diphtheria bacilli, especially in the nose, has been commented on by Boissard and Fry (1941, 1942).

We have already noted the effect of closeness of contact on the carrier rate. It may be added that the investigation of epidemics in institutions suggests that this factor is of great importance, both in regard to the production of carriers and of actual cases of disease. It would seem that duration of contact must be considered as one aspect of this problem; and there is good evidence that contact of the type which is exemplified by the case of boys sleeping in a single dormitory is enormously more important than casual or momentary contact during working hours (Dudley 1923).

In concluding this section we may consider the importance of *fomites* in the spread of diphtheria. From the case of the child's box of bricks, reported by Abel in 1893, there have been instances in which it seemed possible to incriminate a particular article as a disseminator of infection. Very occasionally, as in the case of the common supply of penholders for a number of schoolboys recorded by Dudley (1923), it would appear that such a mode of transmission may have played a significant part. In general, however, the balance of evidence would appear to be heavily against the view that fomites play any significant rôle in the spread of the disease; and there is nothing to suggest that stringency of disinfection would make any appreciable impression on its incidence. An exception must, however, be made for *dust*, which observations by Wright and his colleagues at Liverpool (Wright, Shone, and Tucker 1941, Crosbie and Wright 1941) have shown

to be a grave source of danger in hospitals and other institutions. Crosbie and Wright were able to isolate diphtheria bacilli in large numbers from floor dust in the neighbourhood of diphtheria patients, and to show that they might remain fully virulent for as long as five weeks. They are of the opinion that floor dust distributed by sweeping and blanket dust liberated during the making of beds may play an even more important part in cross-infection in diphtheria wards than the direct transmission of droplets from patient to patient. Measures to reduce aerial infection by dust, such as the application of heavy oil to the floors (van den Ende, Lush and Edward 1940, Thomas 1941) and to the blankets (van-den Ende and Thomas 1941) hold out some promise of success, though so far no simple method for destroying diphtheria bacilli in the dust itself has yet been devised.

The Spread of Diphtheria by Domestic Animals.—It was at one time believed that certain domestic animals played a significant part in the spread of diphtheria, but most of the evidence on which this belief was based has been shown to be erroneous. It is now clear that Klein's (1889) statements with regard to diphtheria in the *cat* were incorrect, and Savage (1919–20) has shown that this animal is extremely resistant to infection by feeding, by intranasal injection, or by swabbing the throat with living culture. There is, indeed, little evidence that it ever contracts or transmits the disease, though one or two suggestive cases have been recorded by Simmons (1920). The domestic *fowl* was credited with similar malign potentialities, a belief that probably arose as the result of a superficial similarity between "fowl diphtheria" and the human disease. The fowl disease is now known to be caused by a filtrable virus, and the generally accepted view is that fowls can be disregarded as a potential source of infection. A report by Litterer (1925) does, however, suggest that these birds may sometimes harbour virulent *C. diphtheriæ*. In two instances he isolated diphtheria bacilli from the throat of several fowls, kept by families among which a case of diphtheria had occurred. The bacilli were fully virulent as tested by the inoculation of guinea-pigs, controlled by protection with diphtheria antitoxin. Some of these fowls were obviously ill, and showed typical membranes. They recovered rapidly after injection with antitoxin. Attempts to reproduce the disease in healthy fowls by swabbing the throat with virulent *C. diphtheriæ*, with or without previous scarification, were uniformly unsuccessful. Thirty fowls suffering from roup were treated in a similar manner. In five cases a typical membrane was produced. If similar results are recorded by other investigators it may be necessary to consider the possibility of the fowl playing some part in the spread of the disease in exceptional circumstances; but it seems altogether unlikely that this part is a significant one from the epidemiological point of view.

We have referred (see Chapter 49) to the occasional isolation of virulent diphtheria bacilli from the *horse*, but here again there is no evidence that such infection has any appreciable effect on the incidence of the disease in man.

Similarly, the demonstration by Ramon and Erber (1934) and by Dold and Weigmann (1934) of virulent diphtheria bacilli in the throats of *monkeys* has little significance in relation to human infection under ordinary conditions of life.

The *cow* is in a different category, since the general consumption of milk renders any infection of this animal of particular importance. The earlier records of diphtheria in the cow may be safely disregarded, since the nature of the disease was never fully established, and the conditions described were, in most instances,

subsequently shown to be due to quite different causes. It is now reasonably certain that the cow does not naturally suffer from any form of infection with *C. diphtheriæ*, and that the only lesion in this animal which has any significance in the spread of the disease is the occasional infection of pre-existing superficial lesions on the teats from the hands of a milker who is suffering from the disease, or is carrying virulent bacilli. The existence of these lesions has been recorded by Dean and Todd (1902), Ashby (1906) and Henry (1920), and the authors have met with one instance of this condition. In all cases the virulence of the bacilli has been established. Such infected wounds, when they occur, are of obvious importance as forming a persistent focus from which the milk is likely to be infected; and in the cases recorded the lesions have been detected during the investigation of a milk-borne epidemic. In the majority of the cases in which an epidemic of diphtheria is traceable to an infected milk supply it is probable that the original source of the bacilli has been a human carrier, who has handled the milk at some time during its preparation.

It may be added that the incrimination of the milk rests, in almost all instances, on epidemiological evidence. The isolation of *C. diphtheriæ* from milk, even when a particular supply is under grave suspicion, has in the past been very uncommon; nevertheless a few successful results have been reported (Bowhill 1899, Eyre 1899, Marshall 1907, McSweeney and Morgan 1928). With the introduction of tellurite medium the technical difficulties of isolation are greatly reduced, as is shown by the reports of Fry (1941) and Goldie and Maddock (1943). There remains, however, the difficulty that the actual milk which conveyed the infection is seldom, if ever, available for examination at the time when attention has been drawn to it, so that unless the contamination continues for some days an infected sample is unlikely to be forthcoming. It must be emphasized that the identification of a diphtheria-like bacillus isolated from milk requires the most stringent tests. No organism derived from such a source should be reported as *C. diphtheriæ* until its character has been established by a properly controlled virulence test.

Prophylaxis in Diphtheria.

Our present methods of controlling diphtheria as a herd disease depend on the isolation of patients, the segregation of recognized carriers, and prophylactic immunization. The last method comprises both active immunization by means of an antigenic preparation now usually referred to as diphtheria prophylactic, and passive immunization conferred by the injection of antitoxic serum. Passive immunization, because of its transitory nature, has a very restricted application and will be dealt with later (p. 1401). For all ordinary field purposes active immunization is employed. An adequate understanding of the principles that govern the application of this method to the control of the disease is so important to the medical practitioner and the medical officer of health that the relevant data must be set out in some detail. We shall begin by describing the various forms of diphtheria prophylactic and their standardization, proceed to a consideration of their application under varying conditions in practice, and then discuss some of the results that have followed their use in mass immunization.

The Various Forms of Diphtheria Prophylactic.

As early as 1892 von Behring and Wernicke showed that susceptible animals might be safely immunized by inoculating them with increasing doses of living

culture after a protective dose of antitoxic serum. Six years later Nikanaroff reported successful results from the inoculation of a few doses of toxin neutralized with antitoxin; and Dreyer, in 1900, proposed the use of toxin-antitoxin mixtures during the early stages of antitoxin production in horses. For various reasons there was a long lag before similar methods were applied to man; and it was not till 1913, when von Behring reported the successful use of a toxin-antitoxin mixture for the immunization of children, that inoculation against diphtheria entered the field of prophylactic medicine. From then onwards the use of such mixtures for the active immunization of children developed very rapidly, particularly in the United States under the influence of Park and Zingher (Park 1913, 1918, 1922, Park and Zingher 1915, 1916, Zingher 1921, 1922). Toxin-antitoxin mixtures were found to be not without danger (see Park and Schroder 1932), and after the discovery by Glenny and Südmersen (1921), Glenny and Hopkins (1923), and Ramon (1923, 1928) that diphtheria toxin could be so altered by treatment with formalin as to deprive it of its toxicity without destroying its antigenic power, formol toxoid, or anatoxin as it is called in French-speaking countries, gradually began to replace the older mixtures. The further demonstration by Glenny (1930) that formol toxoid could be improved by precipitation with alum has now placed at our disposal an agent of high antigenic potency which, when properly prepared and used, can be relied upon to give a fairly high degree of protection against diphtheria.

Toxin-Antitoxin Mixture.—In preparations of this class sufficient antitoxin is added to neutralize the toxic effects of the toxin without completely destroying its antigenic activity. The toxin, that is to say, is under-neutralized. Though very satisfactory results have been obtained by the use of such mixtures, a few accidents have shown that the union of toxin and antitoxin is unstable and is liable to be disturbed by unsuitable methods of preparation or of storage. In one instance, in which 5 deaths and 40 serious reactions followed the use of this prophylactic (see Forbes 1927), it was found that, in forgetfulness of the Danysz phenomenon, the toxin had been added in fractions to obtain the correct toxin-antitoxin ratio. In another instance a particular phial of toxin-antitoxin mixture that had been frozen was found to have caused severe constitutional reactions, whereas other phials of the same batch that had not been frozen had been used without any untoward results. Further investigations revealed that the freezing of such mixtures frequently resulted in a considerable rise in toxicity. Pope (1927) has shown that this phenomenon is dependent, in part at least, on a separation of the phenol during freezing; this leads to a local concentration greatly in excess of the 0·5 per cent. or so added for preservative purposes, and to a consequent destruction of antitoxin, which is more sensitive than toxin to phenolization. Observations recorded by Robinson and White (1928) indicate that, even in the absence of added phenol, dissociation of toxin-antitoxin mixtures may occur on freezing, the degree of dissociation depending apparently on the concentration of the mixture. A dose of toxin equivalent to 12 M.L.D. for a guinea-pig may be fatal to a child (Schmidt 1942).

Formol Toxoid. F. T.—This is prepared by treatment of culture filtrates with formalin in a concentration depending on the amount of amino-nitrogen present. The pH of the toxin is adjusted to 7·4–7·6, and the formolized mixture is incubated for 3–4 weeks at 37–38° C. until the product, as judged by the intracutaneous inoculation of guinea-pigs and rabbits, is devoid of all residual toxicity (Barr, Pope, Glenny and Linggood 1941). The chemical changes involved in the conversion of toxin into toxoid are still imperfectly understood, but reference may be made to the observations on this subject of Kissin and Bronstein (1928, 1930), Hewitt (1930), Bunney (1931), and Schmidt (1933*a*, *b*, *c*).

Toxoid-Antitoxin Mixture.—The addition of antitoxin to formol toxoid is an empirical attempt to obtain a reagent that induces an effective immunity without causing a troublesome local reaction, as formol toxoid alone may do, and without running the risk of danger following possible dissociation, such as attends the use of a toxin-antitoxin mixture. It has been developed mainly in Great Britain; in the United States its advantage over simple formol toxoid has always seemed questionable. It is frequently designated T.A.M., but since this abbreviation is also employed by some workers for toxin-antitoxin mixture, it is better avoided unless the particular prophylactic to which it is intended to refer is specifically mentioned.

Toxoid-Antitoxin Floccules. T.A.F.—This is a suspension of the precipitate of floccules that are formed when toxoid and antitoxin are mixed in appropriate neutralizing amounts. The elimination of much of the non-specific serum protein and bacillary products present in toxoid-antitoxin mixtures results in a product that combines effectiveness with a minimum of unpleasant local effects (see Glenny and Pope 1927, Swyer 1931, Dudley 1932, Underwood 1934, and others).

Alum-Precipitated Toxoid. A.P.T.—The use of alum-precipitated toxoid for active immunization in man followed the demonstration by Glenny (1930) that this reagent was extremely effective in inducing immunity in experimental animals (see also Glenny and Barr 1931, Glenny *et al.* 1931). Its high potency appears to be due to delayed absorption of the precipitated toxoid from the site of inoculation, with a consequent prolongation of the antigenic stimulus. It consists essentially of a suspension of the washed precipitate produced by the addition of alum to formol toxoid. Considerable care has to be exercised over its preparation, and exposure of the toxoid to acid or to phenol, such as is inherent in the method described by Watson, Taggart, and Shaw (1941), must be avoided (Glenny *et al.* 1926, Hartley 1935*a*, Barr *et al.* 1941). Fortunately Glenny and his colleagues (Barr, Pope, Glenny and Linggood 1941) have provided a detailed description of how A.P.T. should be made, and the resulting product has been proved by field trials to be both effective and reliable (see also Pope and Linggood 1939, and Seal and Johnson 1941 on purification of toxoid and A.P.T.).

Active Immunization.

To produce a high degree of immunity against diphtheria by prophylactic inoculation, account must be taken of the nature of the prophylactic, the dosage, and the interval between the doses. Other factors, such as the latent immunizability of the population (Dudley, May, and O'Flynn 1934), and possibly the volume of the fluid in which the prophylactic agent is injected (Hartley 1935*b*), may influence the result, but need not be considered here.

Of chief importance is the *antigenic quality of the prophylactic*. As was pointed out in the last section, methods of standardization are still imperfect, and unless a high standard is set, batches of prophylactic may be issued that are unable to stimulate a satisfactory immune response. Even an increase in dosage as much as fivefold may fail to atone for a qualitatively poor antigen (Fulton *et al.* 1942). To Schick-positive subjects who do not react to heated toxin the same *dosage* may be given irrespective of age. In Schick-negative subjects who are being given a single re-inforcing dose, and in Schick-positive subjects who give a pseudo reaction or a Moloney reaction (see p. 1396), it is usually wise to inject a smaller dose in older children and adults than in young children. Toxin-antitoxin and toxoid-antitoxin mixtures, toxoid-antitoxin floccules, and formol toxoid are best administered in three doses at 3-week intervals, the first two in doses of 0·5, 1·0 and 1·0 ml., T.A.F. in 1 ml. doses, and F.T. in doses of 0·2–0·5 ml., 0·5 and 1·0 ml. Alum-precipitated toxoid can be safely relied upon to produce a corresponding,

or even higher, degree of immunity in two doses of 0·2 and 0·5 ml. at 4-weeks' interval. In the early days it was often used in a single dose of 0·5–1·0 ml., but experience showed the results to be unsatisfactory, and the method is now seldom recommended except in special circumstances (see Report 1940).

The choice of prophylactic and the dosage are determined partly by their immunizing power and partly by the local or constitutional reaction to which they give rise. Though exact comparative data are lacking, there is reason to believe that toxoid-antitoxin mixture and toxoid-antitoxin floccules cause the least tissue reaction and that alum-precipitated toxoid causes the most. In general, therefore, it is wise to use the former for Schick-negative subjects, for pseudo-reactors, and for adults whose Schick-reaction is unknown, and to use formol toxoid, or preferably A.P.T., for the rest.

The *interval between the doses* has been shown by numerous workers to play a decisive part in determining the degree of antibody response (for references see Lewis 1941). In a Schick-positive subject who has had no previous experience of the diphtheria bacillus, the first dose of prophylactic has the effect merely of sensitizing the antibody-forming apparatus. The second dose, provided time has been allowed for adequate sensitization to take place, is followed rapidly by the appearance of antitoxin in the circulating blood and the conversion of the Schick-positive to the Schick-negative state. Sensitization is a slow process and till it is complete the full effect of the second dose of antigen will not be experienced; once, however, it is established, it is relatively immaterial how long the second dose is delayed.

Several careful studies have been made on the efficacy of different types of diphtheria prophylactic, as judged by the Schick-conversion rate or by the amount of antitoxin appearing in the blood serum (see, for example, Park and Zingher 1915, 1916, Park 1922, Ramon 1926, Kundratitz 1927, Parish and Okell 1928, Martin, Loiseau, and Laffaille 1928, Ramon and Debré 1931, Seligmann 1931, McGinnes, Stebbins, and Hart 1934, Haine 1935, Fraser and Halpern 1935, 1937, Jensen 1937, Faragó 1940, and for references to results of two doses of A.P.T Pöch and Schmid 1938, Chesney 1939, Fulton *et al.* 1941, Lewis 1941, Volk and Bunney 1939, 1942*a*, Freeman 1942). The findings may be summarized by saying that two properly spaced doses of A.P.T. result in an average Schick-conversion rate of about 98 per cent., whereas with other prophylactics this high rate may be closely approached, but is seldom equalled.

The *duration of immunity* is dependent not only upon the type of prophylactic, but upon the subsequent exposure of the inoculated subject to infection with the diphtheria bacillus. In a community in which there is much diphtheria or a high carrier rate the immunizing mechanism is likely to receive more or less frequent stimuli, which will have the effect of re-inforcing the immunity conferred by the prophylactic. On the other hand, in communities with little or no experience of diphtheritic infection, the antitoxin content of inoculated subjects may be expected to fall progressively (see Jensen 1933*a*, *b*) and the Schick reaction to revert to positive. It is not surprising, therefore, that the results recorded by different workers are not in complete accord. Some observers, for example, like Park (1922), working in densely populated cities, have had few Schick relapses over a period of many years, whereas others, working in areas where there has been little diphtheria infection, have had high relapse rates. Thus Fraser and Brandon (1936), in Canada, found that of children who had received three doses of formol toxoid five years previously, and who had not been exposed to infection

since, 34 per cent. had reverted to the Schick-positive state. Similar results are recorded by Schwartz and Janney (1938) and Volk and Bunney (1942*b*) in the United States, and by Sigurjónsson (1939) in Iceland (see also Parish and Okell 1928, Cooke 1936, Jones 1936-37, Christie 1940, Nevius and McGrath 1940, Duke and Stott 1943). Generally speaking, we may say that in children properly immunized with two doses of A.P.T. and not exposed to diphtheritic infection the Schick-relapse rate should not exceed 5 per cent. per year. Since immunity cannot be relied upon to last indefinitely, it is wise to reinoculate children every 4 or 5 years. For this purpose a single dose of prophylactic is sufficient, since there is abundant evidence to show that a single re-inoculation of persons, even of those who have relapsed to the Schick-positive state, is followed by a rapid rise in the antitoxin content of the blood (see Parish and Okell 1928, Parish and Wright 1938, Fraser 1940, Volk and Bunney 1942*b*, Wishart *et al.* 1944). In this connection it may be noted that many patients who have recovered from diphtheria remain Schick-positive (see Warin 1940). Since second attacks of the disease are not uncommon, such persons may be regarded as susceptible, and inoculated or re-inoculated with the rest. Why an attack of diphtheria is not always followed by immunity is still doubtful. That it is not due mainly to suppression of the antibody-forming mechanism by the administration of large quantities of antitoxin therapeutically seems clear from Madsen's (1939) observation that 13 out of 26 untreated patients failed to form detectable antitoxin as the result of their attack.

The desirability of a *preliminary Schick test* to find out whether inoculation is required, and of a subsequent Schick test to find out whether immunization has been successful, is open to question. Space does not allow a full discussion of the subject, and we must therefore restrict ourselves to a summary of the conclusions we have reached from our own observations and from those of other workers.

In a mass immunization campaign a preliminary Schick test, entailing as it does two inoculations and an extra visit for each child, seems to us to be justified on only two conditions, firstly that a high proportion of the children are Schick-negative, and secondly that inoculation is restricted to Schick-positive reactors. In areas in which diphtheria has not been prevalent and in which inoculation has not been widely practised, a high proportion of the children are generally found to be Schick-positive. Under such conditions Schick-testing is wasteful of both time and material. It is all the more so if, as many experienced workers recommend, the Schick-negative reactors are inoculated at the same time, usually with a single dose, to reinforce their failing immunity. For practical purposes, therefore, we see no advantage in carrying out a preliminary Schick test on a pre-school or school population. The susceptible members require inoculation anyhow, and the immune members will come to no harm through being given two doses of prophylactic but will, on the contrary, have their immunity strengthened.

In adults, the position is different. Mass immunization is seldom called for, so that the extra time required for a preliminary Schick test is a less important consideration. A fairly high proportion will probably be found to be immune; and the argument for inoculating adults who are Schick-negative is not so strong as for children who are still at an age when susceptibility is relatively great. An even more important factor, however, is that the inoculation of adult Schick-negative or pseudo-reactors with full doses of prophylactic, especially A.P.T., is likely to be followed by a severe local and even constitutional reaction. It is

wise, therefore, before inoculating adults, to carry out a preliminary Schick test, and to restrict inoculation to Schick-positive reactors, unless the subject is, like a doctor, nurse, or school teacher, likely to be exposed to an unusually high risk of infection; for such persons a single inoculation with half the usual first dose is recommended. To test the subject's sensitivity to formol toxoid, the Moloney test (Moloney and Fraser 1927) may be carried out either in addition to the Schick test or in place of the heated toxin control. An injection of 0·2 ml. of a 1/20 dilution of formol toxoid is made intradermally. Any person giving more than a minimal local reaction should be immunized very cautiously. In practice, however, this test is seldom needed.

For the mass immunization of children, alum precipitated toxoid, injected in doses of 0·2 and 0·5 ml. at 4-weeks' interval, is the prophylactic of choice. For adults likewise, A.P.T. may be used provided it is confined to Schick-positive reactors (see Leete 1942). Less reaction, however, is likely to be experienced from T.A.F.; this should be given in three doses of 0·5–1·0, 1·0, and 1·0 ml. at intervals of 3 weeks (Circular 1942).

By itself a *post-inoculation Schick test* is of value in learning whether the child has been satisfactorily immunized. It is carried out best 2–4 months after the last inoculation, when the antitoxin content of the blood is at its height. Though such a test may often be usefully applied to persons who are exposed to special risk of infection, it is seldom justifiable in mass immunization campaigns. There is, however, a strong case to be made out for testing a sample of the inoculated population in order to gain assurance that a high proportion, such as 98 per cent., have responded satisfactorily. So many variables enter into the development of Schick-immunity that this should never be taken for granted.

To compare the antigenic potency of two different prophylactics or of different modes of administration of the same prophylactic, it is desirable to estimate the *Schick-conversion rate*. This necessitates preliminary as well as post-inoculation Schick-testing, and is calculated on the proportion of Schick-positive subjects in each group that are rendered Schick-negative. Unless a preliminary test is made, the proportion of original Schick-negative reactors in each group is unknown, and a difference in their distribution will affect the result of the comparison.

The Protective Effect of Active Immunization.

Though a high Schick-negative or Schick-conversion rate affords a strong presumption that satisfactory immunization has been achieved, the ultimate court of reference in determining the efficacy of prophylactic inoculation must be the behaviour of immunized persons when exposed to the risk of natural infection.

Bieber (1920) reported the after-history, from 1913, of 1,097 immunized and 3,275 non-immunized children in villages near Magdeburg. Of the former, 52 (4·8 per cent.) had contracted diphtheria; of the latter, 493 (15·1 per cent.). Park (1922) records the history over a shorter period of 90,000 immunized or naturally immune children and 90,000 controls. During the period of observation 14 of the former contracted diphtheria as against 56 of the latter. Adams (see Fitz-Gerald 1928) records the history during the years 1926 and 1927 of 11,000 children who had received two immunizing doses of toxoid, and of 9,000 non-immunized controls. Among the immunized the incidence of diphtheria was 1·55 per 1,000, among the non-immunized it was 11·44 per 1,000. Isabolinski and others (1931) describe the results of immunization in Smolensk. Of 4,185 children immunized with toxoid, 0·14 per cent. contracted diphtheria during the eleven months following immunization; of 19,000 control children in the same town 1·5 per cent. con-

tracted diphtheria during the same period. McKinnon and others (1931) and Fitz-Gerald and others (1932) record the results of immunization in Toronto. Among a group of 36,189 children who had passed through the immunization centres and had been found to be Schick-negative, or had received one or more immunizing doses of toxoid, or had been found to be sensitive to a preliminary injection of toxoid and so received no further treatment, there were 120 cases of diphtheria during the period of observation (December 1926–June 1929). As a control the prevailing rates of diphtheria morbidity at ages among the non-immunized population were applied to each age group of the immunized. This gave 478 as the expected number of cases. Of the 36,189 children, 16,829 had received three doses of toxoid. Among this group 222 cases of diphtheria would have been expected; only 23 occurred. There are many other records of an analogous kind (see Forbes 1932). More recently, in Scotland, there were 2,833 cases of diphtheria and 13 deaths among about 750,000 immunized, and 17,091 cases and 794 deaths among rather less than half the number of non-immunized persons. The risk of contracting diphtheria was about 14 times less in the immunized than in the non-immunized, and the risk of contracting fatal diphtheria was over 100 times less (A. Russell 1943).

Still more demonstrative evidence is obtained if we confine our attention to groups of persons who are exposed to an unusually high risk of contracting diphtheria. Fever hospitals supply an environment in which such a risk occurs, and the history of attempts to immunize the nursing and domestic staff is correspondingly instructive (see, for instance, Benson 1928, Woods 1928, Harries 1930). We may take the figures given by Harries for the Birmingham City Fever Hospital as an illustrative example (Table 117).

TABLE 117

SHOWING THE DIPHTHERIA INCIDENCE AMONG THE NURSING AND DOMESTIC STAFF AT BIRMINGHAM CITY FEVER HOSPITAL. (Modified from Harries.)

Year.	Diphtheria Incidence per cent.		
	Nursing.	Domestic.	Combined.
1919	15·6	9·4	13·5
1920	24·5	16·3	21·8
1921	13·0	11·1	12·4
1922 (*a*)	6·5	6·7	6·5
1923 (*b*)	3·7	8·9	5·2
1924	0·93	11·1	3·9
1925 (*c*)	—	—	0·77
1926	—	—	0·76
1927	—	—	0
1928	—	—	0
1929	—	—	0·6

(*a*) Schick testing of nursing staff commenced.
(*b*) Active immunization of nursing staff commenced.
(*c*) Active immunization of domestic staff commenced.

The significance of such figures cannot be in doubt. The decline of diphtheria among the nurses coincident with the commencement of Schick testing and immunization, the persistence of diphtheria among the domestic staff until similar measures were applied to them, and the subsequent lowering of incidence until, during 3 years, only 1 case of diphtheria occurred among a staff increasing from 130 to 166, indicate clearly that adequate immunization of all susceptibles will

reduce to insignificance the incidence of this disease among a community exposed to particularly severe risks.

Orphan asylums, children's homes and boarding schools, where persons of a susceptible age are congregated together, afford another example of an environment in which the risk of infection is above the average; and the experience in such institutions confirms that obtained in fever hospitals. Nassau (1930), for instance, records the effect of active immunization in a children's home near Berlin; and Dudley (1923, 1926, 1932) has provided a very fully documented account of the control of diphtheria in the Royal Naval School at Greenwich.

There is, then, no reasonable doubt that active immunization, properly performed, is highly effective in protecting the individual against diphtheria, and in eliminating diphtheria from any small closed community in which all the susceptible inmates are immunized. Emphasis, however, must be placed on the word "properly." This implies using a high-quality prophylactic in adequate dosage with a suitable interval between the doses, controlling the effect by Schick-testing a sample of the population subsequently, and giving a re-inforcing dose at 4- or 5-year intervals till the child is 15 years of age. Unless these conditions are complied with, cases of diphtheria and even occasional deaths, may be expected to occur, as the experience of Glover and Wright (1942) at Liverpool shows. It may be noted that in the instances in which infection in an immunized person, or in a fully immunized community, has been recorded, the infection has nearly always been of the *gravis* or *intermedius* type, and the case mortality has been considerably less than in non-immunized persons (see Dudley *et al.* 1934, Parish and Wright 1935, Glover and Wright 1942).

The Results of Mass Immunization.

We may now turn to the question whether prophylactic inoculation, controlled when necessary by Schick-testing, will reduce significantly or eliminate altogether the incidence of diphtheria in the community at large, if applied on the widest possible scale. It must be realized that the emphasis is on the final limiting clause. There is no reason to doubt that, if all susceptibles in the community could be immunized, the reduction in the incidence of diphtheria would be of the same order as that attained in closed or semi-closed communities. But we are dealing with practical politics, and what we want to know is the probable effect of an administratively possible policy. We are here faced with a problem of great statistical difficulty. It will not do to cite a few instances in which the inauguration of mass-immunization of school children has been associated with a decline in the general diphtheria morbidity rate, because we know quite well that most infective diseases are subject to secular trends in frequency, and a falling rate for any one of them might well have no significant association with any particular preventive measure adopted at the time the fall occurred.

Woods (1928), for instance, has pointed out that the fall in the diphtheria morbidity rate which followed the introduction of mass immunization in New York in 1918 cannot be accepted as certainly significant. The rate was already falling before the immunization began; and if a straight line is fitted to the trend of mortality for the years prior to 1917, and is then extrapolated beyond 1918, this extended line approximates very closely to that which would describe the actual course of events during the following decade.

Godfrey (1932), in an admirable review of the available evidence, discusses the possible reasons for such divergent results as those recorded in New York City and Philadelphia, where immunization was followed by a marked decrease in morbidity, and in Newark,

Detroit and Buffalo, where similar measures failed. Tracing in detail the course of events in eleven different districts in New York State he arrives at the conclusion that the crucial point is to be found in the immunization of the child of pre-school age (the age group 1–5). The earlier attempts at mass immunization were, for obvious administrative reasons, confined mainly to children of school age (the age groups 5–9 and 9–14). Godfrey can find no evidence that the immunization of 50 per cent. or over of the children in these age groups produces a definite fall in the incidence of diphtheria in the community as a whole. When, however, the immunization of 30 per cent. or more of the age group 1–5 is superimposed on that of the later age groups there is an immediate and striking decline in the general prevalence of the disease. Godfrey found only two exceptions to this rule in the eleven areas from which his data were obtained.

The same point is made by Lee (1931) who has studied the trend of diphtheria mortality in Philadelphia and in New York City from 1870 to 1930. Fitting an exponential curve to the recorded death rates, he finds that for neither city was there any significant departure from the general trend between the end of the period (1890–1900), when the use of antitoxin as a therapeutic measure was becoming general, and 1929. But in 1930, following the extension of the immunization campaign to children of pre-school age, there was a dramatic change in both cities. In Philadelphia the expected death rate on the basis of the previous trend would have been 10·5 per 100,000, with odds of 20 : 1 that it would fall between 8·1 and 13·6. Actually it was 2·86. In the case of each city the odds against the observed difference between the actual and the expected death rates being due to chance are enormous. (See also Deadman and Elliott 1933.)

In summary, we have in the modern method of antidiphtheria immunization a measure that is based on well-attested immunological principles, involves the use of a reagent of proved potency, is supported by the results of numerous animal experiments, has been shown to be effective in raising the resistance of the individual and in controlling the incidence of the disease in isolated or semi-isolated communities, and is almost certainly capable of greatly reducing the incidence in the community as a whole, if due attention is paid to herd reactions.

It is possible that the effect of immunizing children of school age alone may be offset, so far as its influence on the *general* morbidity is concerned, by the creation of healthy carriers who may infect the younger susceptibles in their homes. We have, here, an admirable example of the necessity for considering the factors that determine herd immunity as well as those that determine immunity in the individual. These factors are very difficult to analyse. The results of a recent survey in the United States and Canada are summarized in Table 118.

Many of the figures given are probably subject to a considerable sampling error; nevertheless the differences between them are often so great as to leave no doubt of their significance. No constant relationship is evident between either the proportion of children immunized, the proportion of Schick-positive reactors, or the carrier rate of virulent diphtheria bacilli to the morbidity from clinical diphtheria. Cleveland, for example, with about the same proportion of susceptibles and the same carrier rate as Virginia, had a morbidity rate 40 times less. Alabama, with only 9 per cent. of susceptible children, had a morbidity rate 12 times as great as Kingston, which had 3 times as many susceptibles. Schuman and Doull (1940) estimate that during 1937–39 in Cleveland there were about 500 carriers of virulent diphtheria bacilli to every case of clinical diphtheria, whereas the corresponding figure given by Frost (1928) for school children in Baltimore in 1921–22 was 47 carriers to each case. Such data as these must make us pause before concluding that immunization alone is sufficient to eradicate diphtheria from a population.

There is here a fascinating problem for investigation, the solution of which is likely to be of both academic interest and administrative importance.

TABLE 118.

RELATION BETWEEN CARRIER RATE AND INCIDENCE OF DIPHTHERIA IN A PARTLY IMMUNIZED POPULATION.

Observations made chiefly during 1937–39.

Observer.	Place.	Approximate Percentage of Children Immunized.	Percentage of Schick-positive Reactors.		Per cent. virulent K.L.B. Carrier Rate in Children.	Morbidity Rate of Clinical Diphtheria per 100,000 Population.
			All Children.	Unimoculated Children.		
Schuman and Doull (1940)	Cleveland, Ohio	80	36	78	0·56	1·67
Stebbins (1940) .	Kingston, N.Y.	77	27	64	0·03	3·5
Fraser and Halpern (1940)	Toronto	? but probably high	?	82[1]	0·04	5·5
Gill (1940) . . .	Alabama	27	9	11	0·87	41·0
Grossmann (1940) .	Virginia	59	30	40	0·5	66·7

[1] Based on antitoxin titrations, regarding persons with less than 1/500 unit per ml. as Schick-positive.

Whether immunization does in fact lead to an increase in the proportion of healthy carriers is a difficult question to answer, since so many other factors are concerned. We are not thinking here of what happens in an institution, but in the general population. Clearly if diphtheria is introduced into an institution containing a high proportion of Schick-negative reactors, there is bound to be a temporary rise in the carrier rate, since the majority of those who become infected will not develop clinical diphtheria and will therefore not be removed to an isolation hospital. In the general population, however, one would expect a different sequence. The fewer cases there are as the result of immunization, the fewer contact carriers will there be, and the fewer carriers there are, the less will be the chance of non-immunes developing diphtheria. On the whole, this assumption is borne out by American experience, where in some towns the carrier rate among the general population has fallen to almost negligible proportions following continued mass immunization. The few figures available in this country are in conformity with the findings in America. Thus, before the second world war the carrier rate in London elementary school children varied between about 2·5 and 5·0 per cent. (see Chapter 56). In September, 1942, however, about 9 months after the beginning of the Government's immunization campaign, the carrier rate of virulent diphtheria bacilli was only 0·38 per cent., and in February, 1943, it had fallen to 0·19 per cent. (Report 1944). These figures lend no support to the suggestion that immunization does more harm than good to the herd by increasing the number of healthy carriers.

Prophylactic Passive Immunization.

To meet particular and transitory emergencies, such as the accidental admission to a children's ward of a child suffering from diphtheria, the subcutaneous or intramuscular administration of 500–1,000 units of antitoxin to each of the other children thus exposed to risk has been found an effective method of stopping the spread of the disease. Provided the children have not been exposed to the infected child for more than 24 hours, a Schick test may be carried out, a preliminary reading taken the following day, and inoculation with serum restricted to those giving a positive reaction. Schick-testing, however, seems to us to be of very doubtful value, unless a high proportion of the children are believed to be immune. Many of the susceptibles will not be read as Schick-positive within 24 hours, and if a longer time than this is allowed to elapse before serum is injected, there is a risk of diphtheria developing. On the whole, it is more satisfactory to give serum to every child. So long as refined serum is used, trouble from serum reactions will be slight.

Combined Active and Passive Immunization, and the Control of Institutional Epidemics.

Combined active and passive immunization consists in giving simultaneous injections into opposite arms of serum and of diphtheria prophylactic, followed later by a second dose of prophylactic. Its object is to stimulate an active immunity under cover of a passive immunity. The doses recommended are 500 units of refined serum and 0·3-0·5 ml. of A.P.T., followed in 2–4 weeks' time by a second dose of 0·5 ml. of A.P.T. This method is of particular value when a case of diphtheria develops in a group of susceptible children in a school, hospital, or other institution, when the extent of the distribution of the infecting agent is unknown, or when further introduction of infection is to be anticipated. In these circumstances passive immunization alone, which wears off in 2–3 weeks, may be followed by the appearance of diphtheria cases due to infection from healthy carriers. The combination of active and passive immunization results not only in a transitory protection of the exposed children, but in the development of an active immunity that can generally be relied upon to prevent further cases of diphtheria developing, even in the presence of continued infection. Since, however, there is an intermediate period of relative susceptibility between the wearing off of passive and the development of active immunity, it is wise to swab the entire population and segregate all virulent carriers till a fortnight after the second dose of A.P.T. By this time sufficient active immunity will generally have developed to render almost negligible the risk of further cases occurring. By this method very successful results have been reported by Fulton, Taylor, Wells, and Wilson (1941) in the control of school and institutional epidemics. To the paper by these authors and to one by Downie, Glenny, Parish, Smith, and Wilson (1941) reference may be made for the rationale and application of combined active and passive immunization.

The advantage of this method in conjunction with swabbing of the entire population and segregation of virulent carriers is that school closure is quite unnecessary, and that, apart from the carriers who are segregated for 6 weeks, every child can continue its normal education. Little is to be gained by preliminary Schick-testing of the population, as was recommended by Okell, Eagleton, and O'Brien (1924) in the days before combined active and passive immunization

was shown to be practicable, and valuable time may be lost. Moreover, the danger of diphtheria developing in Schick-negative reactors who are exposed to special risk of infection is by no means remote. On the whole, we think that there is far more to be gained by giving combined active and passive immunization to all children than by immunizing only the Schick-positive reactors. The time and labour expended are also less.

The Standardization of Diphtheria Prophylactics.

The flocculation test of Ramon (1922) provides an obvious method of determining the amount of toxoid in any prophylactic, and Glenny, Pope and Waddington (1925) found that the immunizing value of a modified toxin was closely related to its Lf value. It has, indeed, become a common practice to state the dose of toxoid contained in a prophylactic in terms of Lf units, when the actual dose of toxoid is stated at all, which is not often the case. But it would obviously be preferable, were it possible, to measure the actual immunizing potency of all preparations by direct comparison with some arbitrarily selected standard reagent.

The technical differences involved in such a comparison are, however, very great. For the reasons discussed in Chapter 43, a comparison carried out on a small number of animals is quite valueless; and, in spite of a few reports in a different sense, it is very doubtful whether the accurate standardization of a reagent used for inducing active immunity is as yet within the realm of practical politics.

The relevant regulations in force in Great Britain, under the Therapeutic Substances Act, are as follows:

"Diphtheria Prophylactic shall be submitted to the following tests:

(*a*) *Tests to determine that the specific toxicity of the toxin used in its preparation has been so reduced that it does not exceed the prescribed maximum.*—Five human doses of the Diphtheria Prophylactic under test shall be injected into each of 5 normal guinea-pigs each weighing 250–350 grammes. This injection must not cause the death of any of the guinea-pigs within 6 days following the injection. If all the guinea-pigs injected survive for 6 days but any of them die within 30 days following the injection from the specific toxæmia, one human dose of the Diphtheria Prophylactic under test shall be injected into each of 5 normal guinea-pigs, each weighing 250–350 grammes. This injection must not cause the death of any of the guinea-pigs within 30 days following the injection.

If a batch of Diphtheria Prophylactic is shown by either of these tests to have a greater toxicity than the maximum hereby indicated, it shall not be issued unless and until the toxicity has been so reduced by further treatment that it does not exceed that maximum.

(*b*) *Test for potency as an immunizing antigen.*—A quantity of Diphtheria Prophylactic not exceeding five human doses shall be injected on one occasion into each of 10 normal guinea-pigs; or, alternatively, a quantity of Diphtheria Prophylactic not exceeding one-tenth of a human dose shall be injected into each of 10 normal guinea-pigs on each of two occasions, separated by an interval of not more than 4 weeks. The guinea-pigs shall be tested for immunity to diphtheria toxin, if they have received the single injection hereinbefore prescribed, at a date not later than 6 weeks after injection, and if they have received the two injections hereinbefore prescribed, at a date not later than 3 weeks after the second injection.

The test for immunity may be made by either of the two following methods:

(i) by intracutaneous injection into each guinea-pig of one test-dose of Schick Toxin. If more than 2 out of the 10 guinea-pigs exhibit a positive Schick reaction, the batch of Diphtheria Prophylactic shall be treated as insufficiently potent, and shall not be issued; or

(ii) by subcutaneous injection into each guinea-pig of five minimal lethal doses of diphtheria toxin. If more than 2 out of the 10 guinea-pigs die as the result of this

injection the batch of Diphtheria Prophylactic shall be treated as insufficiently potent, and shall not be issued."

This, it will be noted, is the prescription of limits of toxicity and antigenic efficiency, not standardization in terms of units.

The standardization of diphtheria prophylactics on laboratory animals is not an altogether satisfactory method for determining the antigenic potency for human beings (see Hartley 1934). It is therefore desirable, whenever possible, to control each batch by field observations on children. For this purpose the Schick-conversion rate is suitable (see, for example, Fulton *et al.* 1942).

Other Diseases caused by Corynebacteria

Besides causing infections of the upper respiratory tract, the diphtheria bacillus may sometimes be found as a secondary invader in skin wounds and in lesions of the vagina. Diphtheroid bacilli of various types have frequently been isolated from the sites of pathological conditions in man. They have been cultivated from the conjunctiva in various forms of subacute or chronic conjunctivitis, from the external auditory meatus in cases of ear disease, from the lesions of acne vulgaris, from other lesions of the skin, from the urine in cases of subacute or chronic urethritis, and from lymphatic glands in a variety of conditions, particularly in lymphadenoma. In a few instances, including perhaps acne vulgaris, the evidence suggests that the association is a causative one, but in the vast majority of cases the early claims to have established an ætiological relationship have broken down in the light of subsequent investigations. There is, as yet, no satisfactory evidence that any corynebacterium, other than *C. diphtheriæ*, with the possible exception of *C. acnes*, plays any significant rôle as a pathogenic parasite of man; though various species form an important constituent of his normal bacterial flora (Andrewes *et al.* 1923, Harris and Wade 1915).

Diphtheroid Infections in Animals.

There are a few diseases which occur naturally in animals other than man, and are caused by infection with corynebacteria.

Ulcerative Lymphangitis of Horses and Pseudotuberculosis of Sheep.—Both these diseases are the result of infection with *C. ovis*, or, as it is more commonly called, the Preisz-Nocard bacillus. The characters of this organism and the lesions that it produces in experimental animals have been described in Chapter 17. It may be noted that this organism, unlike *C. diphtheriæ*, is pyogenic and invasive, as well as toxigenic. The exotoxin produced by it differs from the exotoxin of *C. diphtheriæ* both in the character of the lesions produced in experimental animals and in its antigenic relationships. The pathogenesis of the natural disease in horses and sheep seems to be determined mainly by the invasive and pyogenic activities of the causative organism. The part played by the toxin is at present doubtful. It may be noted that pseudotuberculosis of sheep is an important disease, from this standpoint, in certain parts of the world, particularly in Australia (see Bull and Dickinson 1931, 1933, 1935, Dickinson and Bull 1931, Discussion 1934).

Infections caused by C. pyogenes.—This organism is probably the most important and widespread member of the *Corynebacterium* group found in association with animal disease. It is responsible for suppurative processes, including pneumonia, arthritis, and mastitis in cattle, pigs, sheep, and goats. A weak toxin

is formed, which often gives rise to antitoxin production in infected animals; this may be measured by the power of the serum to inhibit the hæmolysis of rabbit cells by the toxin (Lovell 1939). The toxin may be converted into toxoid by treatment with formalin. An alum-precipitated toxoid induces antitoxin formation in animals inoculated intramuscularly, but whether it will prove of prophylactic value under field conditions remains to be decided (Lovell 1941).

Pyæmia in Foals.—Magnusson (1923, 1938) described a pyæmic disease of foals in Sweden due to a pigment-forming organism, which he called *C. equi* (see p. 469). As a rule the disease is characterized by a suppurative bronchopneumonia, with greyish-red pus in the bronchi, and an intense purulent infiltration of the pulmonary lymph nodes. In some cases intestinal ulceration occurs, accompanied by large abscesses in the mesenteric lymph nodes. Though *C. equi* is often present in the submaxillary lymph nodes of pigs, it does not appear to give rise to lesions in these animals (Karlson *et al.* 1940).

Infections caused by C. renale.—This organism appears to give rise to cystitis and pyelitis in cattle (see p. 461).

Pseudotuberculosis of Mice.—This is a natural disease of mice caused by *C. pseudotuberculosis murium*. So far as it is known, no other animal species is susceptible. Since, in this instance, the animal used for experimental purposes has been the natural host, the lesions of the disease have been described in Chapter 17 (p. 461).

CHAPTER 62

GLANDERS AND MELIOIDOSIS

GLANDERS

NUMEROUS investigators during the nineteenth century brought evidence to show that glanders was infectious; and that the disease in man was the same as that in the horse. The causative agent, however, was not isolated till 1882, when Loeffler and Schütz (Loeffler 1886) succeeded in cultivating *Pf. mallei* from a horse dying of acute glanders. They isolated it in pure culture from the liver and spleen, and produced characteristic lesions in the guinea-pig, rabbit, and field mouse by injection of the bacilli. The organisms were demonstrated histologically in the lesions, and isolated in pure culture.

Epidemiology in Animals.—Glanders is primarily a disease of equine animals. Pigs and cattle are absolutely resistant. Goats, sheep, dogs, and cats sometimes contract the disease naturally; it has also occurred in zoological gardens amongst carnivora, such as lions and tigers, which have been fed on infected horse-flesh.

There are two clinical types of the disease in horses and asses—glanders and farcy. In **glanders,** which may be acute or chronic, the lungs are almost invariably affected. Rounded, greyish, firm nodules, about ½ to 1 cm. in diameter, appear in small numbers—often not more than a dozen or so. They are embedded in the lung tissue, from which they are not easy to enucleate. When recent they have a dirty white centre and a dark red, or sometimes yellow, gelatinous periphery; the central part consists of thick pus. In older nodules the greyish central zone is surrounded by dryish crumbling material, or by a fibrous capsule. In acute cases there may be an actual pneumonic infiltration of the lung. Histologically the young lesions consist of polymorphonuclear cells, surrounded by a zone of congestion. It is stated that, in the older nodules, there is frequently a zone of epithelioid and giant cells around the central necrotic area, and surrounding the whole there is a layer of fibrous tissue. Occasionally calcification may occur (Riegler 1905, Reinhardt 1919). Glanders may invade other organs as well as the lungs, particularly the nasal mucosa and trachea; nodules first appear, which later ulcerate and discharge a greenish-yellow serous fluid, sometimes streaked with blood (Hunting 1908, Hutyra and Marek 1926). The submaxillary glands are often enlarged; subcutaneous abscesses are not uncommon; and in the acute disease nodules are distributed throughout the spleen, liver, and other organs.

In the mule glanders is almost invariably acute, death occurring in 3 or 4 weeks (Mason 1918).

Farcy may result from direct infection of the skin, or it may be a secondary manifestation of glanders. Swellings appear in the skin or subcutaneous tissues, particularly of the extremities and flanks, which break down and ulcerate. The

lymphatic vessels leading from these swellings become firm and enlarged, standing out beneath the skin as hard cords—farcy pipes. These run to the nearest lymphatic glands, which likewise become prominent—farcy buds. Along the course of the lymphatic vessels fresh swellings may appear, so that there may be a chain of nodules connected by firm cords looking not unlike a rosary.

Incidence.—Glanders was at one time widespread throughout Europe, but of recent years, owing to precautionary measures, it has steadily diminished in most countries. It is still prevalent, however, in Russia, where as many as 4 per cent of the horses are said to be infected (Hutyra and Marek 1922). The disease occurs in Asia, Africa, and America; Australia has so far remained free. In Great Britain it was very common previous to the passing of the Glanders or Farcy Order in 1907; since then it has decreased, so that now no more than one or two small epizootic cases are reported (Table 119).

TABLE 119

PREVALENCE OF GLANDERS AND FARCY IN GREAT BRITAIN.

1909 . .	533	1,753 [1]			

[1] Includes horses that reacted to the mallein test, and on post-mortem examination showed glanders lesions.

Both the mule and the ass are very susceptible to glanders, and in them the disease generally takes an acute form. In spite of the high susceptibility of asses, however, these animals do not appear to be as frequently affected as horses and mules. Thus, during the war of 1914–18, Mason (1918) stated that the incidence of glanders in Cairo and Alexandria was approximately 1 in every 4 horses and mules, but only 1 in every 100 asses.

In considering the incidence of glanders, it must be remembered that in many respects the disease resembles tuberculosis. For every clinical case there are a number of latent cases, revealed only by the mallein test or one of the numerous other reactions that are now employed in diagnosis. Occult glanders, in fact, is the rule, not the exception (M'Fadyean 1905). Months may elapse between infection and the onset of symptoms; and in many animals it would appear that the disease may lie permanently dormant, or undergo spontaneous cure. As with

most diseases affecting the respiratory tract, glanders is commonest in cities and in places where large numbers of animals are kept in close contact. During the first 5 years of this century, for example, about 75 per cent. of all cases reported in Great Britain occurred in London (M'Fadyean 1905). The disease used to be especially prevalent in the large studs of horses owned by the Municipal Omnibus Companies; once the infection had been introduced, it spread rapidly throughout the stud. Apart from clinical cases there was an even larger number of carriers, which served to propagate the disease and to render its control extremely difficult.

Mode of Infection.—The mode of infection is not at all clear. Though primary disease of the lung appears to be very common, the belief has grown up that infection does not occur by the respiratory tract. It is difficult to gather from the literature the real incidence of primary glanders of the lung. There are many other diseases that give rise to lesions closely resembling the glanders nodule (Riegler 1905, Joest 1915); and our impression is that in the past many true cases of glanders have been classified under other headings and *vice versa*. Experimentally, most attempts to produce chronic pulmonary glanders *via* the respiratory tract have failed; intratracheal and intranasal injection of the bacilli have resulted in the acute disease. Most workers have therefore concluded that infection does not ordinarily occur by this route. On the other hand, typical pulmonary lesions have followed infection by the mouth (M'Fadyean 1904, Bonome 1906). In animals infected in this way, however, it is usual to find some degree of inflammatory reaction in the intestinal mucosa and submucosa, together with hyperplasia and necrosis of the mesenteric glands. As these lesions are uncommon in horses dying naturally, it is by no means certain that the disease set up in this way corresponds to that occurring spontaneously. Bonome (1906) tries to explain the discrepancy by assuming that the intestinal and mesenteric glandular lesions rapidly retrogress so that in about 2 months only the pulmonary lesions are apparent.

Without discussing this question any further, we may point to the close analogy with tuberculosis, in which much the same arguments have been advanced for and against the respiratory route of infection (see Chapter 59). Whether the infectious material in glanders reaches the lungs by direct inspiration, by absorption through the pharyngeal mucosa, or by passage through the intestine and mesenteric glands, it is impossible to say with certainty. The important point is that the nasal and pulmonary discharges, and sometimes the urine and fæces, of animals suffering from glanders are infectious, and that any other susceptible animal coming into contact directly or indirectly with these discharges is liable to contract the disease.

Reproduction of the Disease.—Farcy may be transmitted by subcutaneous inoculation. Under natural conditions, it is probable that some cases occur by direct infection of the skin—as in grooming—while others are really metastatic infections of pulmonary origin. In nearly every case of farcy, glanders nodules are present in the lungs at necropsy (M'Fadyean 1904).

Glanders may be reproduced in horses, asses, and mules by feeding with cultures of the bacillus, and by subcutaneous inoculation. Sheep and goats are easily infected, but cows and pigs are absolutely resistant. Of laboratory animals the guinea-pig and the field mouse (*Arvicola arvalis*) are the most susceptible to expect mental inoculation; rabbits and dogs are less so; rats, birds, and perhaps white mice, are comparatively resistant. (See Chapter 19.)

Epidemiology in Man.– Glanders in man is uncommon. Robles in 1906 succeeded in collecting reports of 156 cases. It is a protean disease, and probably many real cases that occur are not diagnosed correctly. It may be acute or chronic, and it may be localized chiefly in the respiratory tracts, or in the skin and subcutaneous tissues. In acute glanders there is generally fever, a mucopurulent discharge from the nose, and a degree of prostration out of all proportion to the clinical signs (Bernstein and Carling 1909); a generalized pustular eruption is very frequent. Death invariably occurs in a week or 10 days. In the chronic disease there may be coryza; there may be multiple subcutaneous and intramuscular abscesses, often associated with enlargement of the lymphatic glands and vessels; nodules may form in the mucosa of the respiratory and alimentary tracts, and may break down and ulcerate; necrotic foci may appear in the bones, and in other lesions in the viscera. The disease may remain active for weeks, months, or even years; it is usually but not invariably fatal. Sometimes after apparent recovery the disease may break out again; latent periods up to 20 years have been observed (Bernstein and Carling 1909). The incubation period varies from a few hours to several weeks. (For an account of a case in a veterinary surgeon, see Galger 1913, 1916).

The disease attacks chiefly those who come into close contact with horses such as ostlers, grooms, and coachmen. Infection results most frequently from contamination of a scratch or wound with a glanderous discharge, but primary infection of the nasal mucosa may occur. Several cases of glanders have been reported in laboratory workers; indeed, probably no organism, with the possible exception of *Br. tularensis*, is so dangerous to work with as the glanders bacillus. In the Czernowitz laboratory the disease broke out amongst several members of the staff a few days after the breaking of a centrifuge tube. Numerous other laboratory infections are on record (Bernstein and Carling 1909). When one considers the infectivity of the organism in artificial culture, it is surprising that the disease is not more common amongst those who come into contact with glandered animals. M'Fadyean stated in 1905 that, during the past 12 years, a single firm of knackers in London had dealt with from 800 to 2,000 glandered carcasses; yet not a single case of glanders had occurred amongst the men. There are several statements in the literature suggesting that the virulence of the organism is subject to rapid variation (Gamaléia 1890, Motta 1906, Bernstein and Carling 1909, Dudgeon *et al.* 1918). It may be that the bacilli in chronic lesions of the horse are relatively avirulent to man, in much the same way as they are to the guinea-pig. If this is so, they may be incapable of giving rise to clinical disease. In this connection it may be noted that Babes, while making autopsies on persons who had come into contact with horses and who had died from diseases other than glanders, observed the presence of encapsulated glanders nodules in the internal organs, especially the lungs. This suggests that occult glanders may occur in man as well as in the horse (M'Fadyean 1905).

Diagnosis.

In acute glanders or farcy a microscopical examination should be made of the pus or discharge. Bacilli are fairly numerous in fresh lesions, but may be difficult to find in older ones. Their demonstration in sections of the tissues is often very difficult, and special staining methods have usually to be adopted; the bacilli are more easy to find in smears. Cultures should be put up on agar, glycerine agar,

and potato. If the material is grossly contaminated, it is best to inject it subcutaneously into a guinea-pig, recover the bacillus from the enlarged glands, and inject it intraperitoneally in pure culture into fresh guinea-pigs. In any case the culture should be tested for virulence, and the characteristic Straus reaction noted (see p. 489). Not all strains of *Pf. mallei* are virulent on isolation; sometimes two or three passages have to be made before the typical disease develops (Dudgeon *et al.* 1918). As a rule material from the acute disease in horses proves virulent, but from the chronic disease it is generally avirulent.

The Straus reaction is not diagnostic of glanders; swelling of the testicles and periorchitis may occur after injection of guinea-pigs with organisms of the *Brucella* group, with *Actinobacillus lignieresi*, with Preisz-Nocard's *C. ovis*, with *Pf. whitmori*, and with a few other species less commonly met with.

Mallein Test.—This is used for the diagnosis of latent or chronic glanders in horses. Mallein is prepared by growing the glanders bacillus in flasks of peptone veal broth containing 4 per cent. of glycerol. After 15 to 20 days' incubation the cultures are sterilized in the autoclave, concentrated to one-tenth of their volume in a water-bath, and filtered through paper (Nocard 1895). The resultant product is a syrupy brown liquid; before injection, this crude mallein has to be diluted about 1/10 with sterile water or 0·5 per cent. phenolized saline. The *subcutaneous test* is made by injecting 2·5 ml. of the diluted mallein under the skin of the neck. Sometimes mallein is prepared by simple filtration, without concentration, of a broth culture; in this case 1 ml. is used for injection. A positive reaction is characterized by (1) a local swelling, congestion, and œdema, often very extensive and painful, appearing some hours after the inoculation, increasing for 30 to 36 hours, and lasting for a week or more; it never suppurates; (2) a systemic disturbance, with a rise of temperature, dullness, depression, shivering, anorexia and other symptoms of illness; the temperature rises about the 8th hour, reaches its maximum from the 10th to the 18th hour, and subsides after 36 or 48 hours. The interpretation of the reaction is largely a matter of experience. Generally speaking, a marked local reaction with a rise of temperature of 2° C. or over can be considered positive. A rise of only 1° to 2° C. may be accounted positive if the local reaction is typical; otherwise it should be considered doubtful. If the rise of temperature is less than 1·0° C., the reaction is negative. A rapid rise of temperature, however high, if succeeded by an equally rapid fall, is of no importance. Old horses may fail to react. In doubtful cases the test should be repeated after 4 weeks. In normal horses the injection of mallein causes a very slight reaction; the small local œdematous tumour disappears in 24 to 30 hours.

A definitely positive reaction, even in the absence of clinical disease, may be taken as proof that the horse is glandered. Extensive use of the reaction has shown that, judged by post-mortem findings, a positive result is correct in about 92 per cent., a negative in 96 per cent. of cases. (For interpretation of the reaction see Babes 1891, M'Fadyean 1893, Bonome 1894, Foth 1894*a*, *b*, Report 1915, Mason 1918, Hutyra and Marek 1926.)

The subcutaneous reaction is inapplicable to horses suffering from fever. It has also the disadvantage that it is sometimes followed by the appearance of antibodies in the blood; hence serological tests cannot be used in horses that have been injected with mallein. For these reasons it has largely been abandoned, and replaced by the cutaneous and the conjunctival tests, which apparently have

no effect on the agglutinin titre of the serum (Lovell 1935). In the *conjunctival mallein test* pure mallein is rubbed on the inner surface of the lids with a soft paint brush. In a positive case the reaction appears 4 to 6 hours later, and has a maximum in 8 to 12 hours, and disappears gradually after 24 to 48 hours. There is a secretion of purulent yellow or greenish-yellow material at the inner canthus, and this overflows and runs down the face. The palpebral conjunctiva is red and swollen. In 50–75 per cent. of the cases a rise of temperature occurs (over 103° F.; Reinhardt 1919). In a negative reaction the secretion, if any, is serous or mucoid. The test is contra-indicated in horses suffering from conjunctivitis and from other diseases in which conjunctivitis may develop spontaneously. Horses recently infected, within 4 to 20 days, do not react, nor do horses with chronic glanders, especially if weak or exhausted. On the other hand, the reaction may be positive in horses that have recovered from the disease. In doubtful cases the test may be repeated immediately.

The *cutaneous mallein test* is not used much; but it is of real value, especially when the conjunctival test is inadvisable or yields a doubtful result. Mallein is rubbed into the shaved and scarified skin on the side of the neck. In a positive reaction there is a marked local swelling. A modification of this method, known as the *intradermal palpebral test*, in which the mallein is injected into the cutaneous surface of the eyelid, was employed during the war of 1914–18. In a positive reaction a sensitive œdema of the eyelid is observed about the 9th or 10th hour after injection, accompanied by conjunctival congestion, a mucous discharge from the eye, and closure of the eyelids. The reaction reaches its height between the 24th and 36th hours, and may persist for 3 or 4 days. In normal animals there may be very slight swelling of the eyelid 2 to 6 hours after injection, disappearing about the 12th hour.

Serological Tests.—The **complement-fixation test** is the most reliable laboratory test for glanders. According to Reinhardt (1919) it gives false positives in 4 per cent. of healthy horses, and false negatives in 2 per cent. of glandered horses. According to Poppe (1919), who reports on 2,669 animals, it gave incorrect results in 0·97 per cent. of cases in which glanders was present, and in 2·21 per cent. of cases in which it was absent. It is stated to be sometimes positive in horses suffering from strangles, horse influenza, or petechial fever, and in emaciated animals not suffering from glanders. It may also be positive in normal donkeys, mules, and pregnant mares.

The **agglutination reaction** is less reliable. Though various workers (see Bourges and Méry 1898, Collins 1908, Nevermann 1910) have regarded a titre of 1/1000–1/2000 as practically diagnostic of glanders, it is quite clear that the serum of perfectly normal horses may react to this level (Wilson 1934, Lovell 1935). Much depends on the agglutinability of the strain used and the technique adopted. Without adequate standardization of these factors, the interpretation of the results of different workers is impossible. As in other diseases, the higher the titre, the greater is its significance. The agglutination test, however, should never be relied on exclusively for diagnosis. Repeated tests are of value; if, in a series of tests at intervals of several weeks, the titre remains the same, it is unlikely that the animal is glandered.

The **precipitin reaction** is not trustworthy enough for practical diagnosis, probably because of the presence of non-specific nucleo-protein substances in the

organisms. Sakamoto (1930) has, however, extracted a soluble polysaccharide from cultures of *Pf. mallei*, with which a specific precipitation test is said to be obtainable.

A number of other tests have obtained prominence during recent years, such as the conglutination reaction, and the combined complement-fixation and hæmagglutination reaction or so-called K.H. reaction of Pfeiler and Scheffler (see Poppe 1919). These reactions are said to be of particular value in the diagnosis of the disease in mules, asses, and pregnant mares, the blood of which not infrequently has a marked anticomplementary action.

It will be realized that a large number of tests are available for the diagnosis of glanders. In practice it is unwise to rely exclusively on any one alone. For ordinary routine work the best combination is the complement-fixation and the conjunctival mallein tests. If these give a doubtful result, the other tests may be employed.

In *mice* the mallein test has been used so seldom that it is difficult to gain any idea of its value. Sabolotny (1926) reports a case in which it was positive. The agglutination test is not very reliable, as the serum of normal persons may have a titre up to 1/100. In glanders it may rise to as high as 1/2000 (Galtier 1881, Collins 1908, Dudgeon *et al.* 1918); but on the other hand it may be extremely low. Several cases have been reported in which no agglutination occurred at all, or only up to 1/60 (Gabriélidès and Remlinger 1902, Bernstein and Carling 1909). The complement-fixation reaction is sometimes of value (Watson 1923, Sabolotny 1926). A leucocytosis is often present in acute glanders (Gabriélidès and Remlinger 1902, Bernstein and Carling 1909).

Immunity and Prophylaxis.

There is a considerable amount of evidence to show that horses may recover spontaneously from glanders (Nocard 1900). Only a small proportion of apparently healthy horses that give a positive mallein reaction subsequently develop clinical signs of the disease (M'Faydean 1900). If they are carefully observed, many of them are found to lose their reaction to mallein. It must be noted, however, that the disappearance of the mallein reaction is no proof of cure (M'Fadyean 1901, Bonome 1906). Spontaneous recovery from glanders does not leave the animals with a high degree of immunity. If exposed to natural infection or experimentally inoculated with glanders material, they not infrequently again contract the disease (M'Fadyean 1900, Nocard 1900, Mohler and Eichhorn 1914).

Numerous attempts have been made to produce an active immunity to glanders. Using graded doses of *morvine*—a substance similar to mallein—Babes (1892) stated that he was able to immunize guinea-pigs. Nicolle (1906) likewise claimed to have immunized guinea-pigs (1) by repeated doses of dead bacilli; (2) by repeated injection of living organisms in very small doses; (3) by a single injection of living organisms in a non-fatal dose. But attempts to render horses immune by vaccination or injections of mallein have not been successful (M'Fadyean 1901). Mohler and Eichhorn (1914) vaccinated horses with 3 or 4 doses of dried bacilli; these animals developed agglutinins and complement-fixing bodies, but were still susceptible to natural and experimental infection with glanders.

Mallein has been tried in the curative treatment of horses and of man; some authors report promising results (Babes, V. 1891, Babes, A. 1892, Pilavios 1893, Bonome 1894), but the mass of evidence does not support their conclusions. It must be remembered that both in horses and in man the disease may retrogress

spontaneously, so that it is difficult to estimate the value of any curative treatment.

Serum therapy has been tried in human glanders (Watson 1923), but the number of cases treated is too small to allow of any conclusions.

For the control of glanders in horses the best results have followed the procedure laid down in the Glanders or Farcy Order of 1907. Briefly this provides that every animal with clinical evidence of glanders, or in every case giving a positive mallein test, shall be regarded as infected with glanders and shall be slaughtered. The diseased carcass shall be buried or suitably destroyed, and thorough disinfection of the infected premises shall be carried out. Contacts shall be tested by mallein, and all positive reactors shall be slaughtered. Since the coming into force of this Order in 1908, glanders in Great Britain has diminished steadily, till now it may be considered as completely eradicated (see Table 11.b, p. 1446).

MELIOIDOSIS

The first descriptions of this glanders-like disease in man were given by Whitmore and Krishnaswami in 1912, and Whitmore in 1913, who encountered it at Rangoon. Clinically it appeared to be a septicæmia or pyæmia; post mortem, suppurating or caseous deposits were found in the viscera. A slender, motile, Gram-negative bacillus was isolated from the lesions which reproduced the characteristic disease in guinea-pigs. The disease has been named Melioidosis by Stanton and Fletcher (1921, 1925), and the causative organism *B. whitmori* (*Pfeiffella whitmori* Pinoy). Melioidosis has been reported not only from Burma and British Malaya, but also from Cochin China, Ceylon, Tonkin and South Africa (see Denny and Nicholls 1927, Pons 1927, Pons and Advier 1927, Mesnard, Joyeux, and Gaulete 1928, Souchard and Ragiot 1933, Roten 1933, Mayer and Finlayson 1944). In their monograph published in 1932 Stanton and Fletcher were able to collect records of 83 cases.

In man the clinical course is brief, death generally occurring within 3 or 4 weeks of the onset of symptoms. A chronic non-fatal case characterized by pulmonary and multiple articular lesions has, however, been described by Mayer and Finlayson (1944). At autopsy the commonest findings are localized areas of consolidation in the lungs, composed of aggregations of small suppurating foci, and abscesses or caseous deposits of varying size in the spleen, liver, and sometimes kidneys. In one case in a European recorded by Stanton, Fletcher, and Kanagarayer (1925), the only lesions were two abscesses in the liver with walls consisting of shaggy necrotic material, resembling those found in amœbic dysentery. In several cases the lesions have been confined to the lungs. Histologically they are indistinguishable from those of glanders.

The disease appears to be primarily one of *rodents*. At Kuala Lumpur in the Federated Malay States, Stanton and Fletcher (1925) stated that it had been present first epidemically and later in a sporadic form amongst their stock of laboratory animals during the previous 12 years. The earliest symptom in rabbits and guinea-pigs is a white milky discharge from the eyes and nose; later dyspnœa occurs, followed by death. At post-mortem in acute cases, there are few signs except yellow miliary nodules on the nasal septum. When the disease has lasted for some time, minute caseous nodules of focal necrosis are found in the lungs, spleen, and sometimes in the liver.

Cases of natural infection have been recorded in wild rats, one case in a cat, and one in a horse. Rodents can be infected experimentally by feeding and by injection of the bacilli into the tissues. (See Chapter 19.)

How man becomes infected is not clear. Some cases have undoubtedly followed contamination of the skin, as in morphia addicts, but Stanton and Fletcher (1932) regard the alimentary tract as the most probable route by which the organisms gain access to the body.

Diagnosis of the disease in man during life is not always easy. The organisms can be cultivated from the blood, from abscesses and sinuses, superficial pustules, and the urine. Splenic or hepatic puncture may be useful for obtaining infective material. In one case Martin (1931) isolated the organism from the cerebrospinal fluid. Suspected material should be cultivated on glycerol agar and inoculated into guinea-pigs. One patient tested gave a positive mallein reaction. Agglutination is not of much value, partly because most patients die before agglutinins have had time to develop, and partly because normal agglutinins to 1/80 or over are sometimes present in healthy persons. At autopsy the organisms can be readily isolated from the visceral lesions. (For general review of the disease see Stanton and Fletcher 1932, de Moor *et al.* 1932, Souchard 1932, Couture 1935.)

CHAPTER 63

CHOLERA

HISTORY.—Though cholera has been endemic in India for centuries, there is no record of its spread to the rest of the world previous to 1817 (Kirchner 1906). Between 1817 and 1823 it invaded many parts of Asia. The second pandemic, 1826–37, was more widespread. Starting in India, it spread to Russia in 1829, and thence to Poland, Germany, Austria, Sweden, and England. Throughout the years 1832–33 the whole of Europe was ravaged. Four thousand deaths occurred in London alone, and 7,000 in Paris. Canada and New York were infected by Irish immigrants fleeing from their native country. The population of Cuba was decimated, and there was a heavy toll of life in Mexico. The third pandemic, 1846–62, again invaded Europe and America. In 1854 the number of deaths in England was 20,000, in Italy 24,000, and in France 140,000. America was infected by way of New Orleans in 1848; thence the disease spread up the Mississippi valley and reached California. In the fourth pandemic, 1864–75, the disease prevailed widely over Asia, Africa, Europe, and America. The fifth pandemic, 1883–96, spread over Egypt, Asia Minor, and Russia; there was a severe outbreak at Hamburg in 1892; and several ports in France, Italy, and Spain were infected. The present or sixth pandemic, which started in 1902, has been confined chiefly to Asia, Egypt, and the Southern countries of Europe. Though the disease has frequently been imported into England and America, since 1873 it has not succeeded in gaining a foothold. With the improved sanitary arrangements of our Western civilization, cholera is being gradually restricted in its field; and it will probably not be long before it is forced back and confined once more to a few endemic foci, such as those in Lower Bengal (Craster 1913*a*, Elkington 1916).

Bacteriology.—At the Berlin Conference of July 1884 Koch (1886*a*) announced his discovery of the causative organism of cholera—the comma bacillus or *Vibrio choleræ*. During the previous year in Egypt and in India he had examined the fæces of 32 patients during life, and the intestinal contents at autopsy of 62 patients who had succumbed to the disease. In not a single instance had he failed to demonstrate the comma bacillus. The organisms were most numerous in the lower half of the small intestine. In acute cases they were present in almost pure culture, but in cases that had lasted longer, and in whom secondary changes had occurred, the vibrios were few and more difficult to find. In a smear from the rice-water stools or the intestinal contents of typical cases, the comma bacilli were arranged with their long axes parallel to one another, presenting a picture similar to that of fish in a stream. The organisms were found in the intestinal contents, in the lumen of the glands, and even between the epithelium and the basement membrane of the mucosa. They were apparently confined to the gut; the mesenteric glands

and the blood were sterile. As a control, Koch examined the intestinal contents of more than 30 cadavers of patients dying from non-choleraic —mostly intestinal —diseases, but he failed to demonstrate the vibrio in a single instance. Though unable to reproduce the disease in lower animals by administration of the vibrio, he came to the conclusion that it was definitely the cause of cholera.

This conclusion was challenged by a number of authorities holding one or other of the multitudinous theories of disease current previous to the bacteriological era. During the next few years their position was strengthened by the discovery of vibrios in all sorts of situations—cheese, dirty well, river and sea water, intestinal abscesses of pigs, diarrhœal faeces of patients with cholera nostras or dysenteric diseases, and other animal and saprophytic sources (see Chapter 22). Since many of these vibrios bore a close resemblance to Koch's comma bacillus, and since their differentiation by means of the morphological, cultural, and pathogenicity tests that were then available was difficult or even impossible, grave suspicion was cast on the ætiological significance of the cholera vibrio.

Later on, however, with the introduction of a more highly specialized technique —especially the agglutination and complement-fixation reactions and Pfeiffer's phenomenon—it was possible to show that the majority of these vibrios differed in one or more essential respects from the comma bacillus. Even then the confusion was not altogether cleared up; for vibrios were isolated from persons who had been in contact with cholera patients, and from water supplies in areas where cholera was epidemic, which, though conforming to the true cholera type in most respects, yet failed to agglutinate with a specific serum. Intensive study of these inagglutinable strains has rendered it probable that many of them belong to the cholera species, but that through the effect of environment they have undergone slight changes which render their identification when first isolated peculiarly difficult. By frequent subculture in the laboratory and passage through the peritoneal cavity of guinea-pigs or mice many of these strains appear to have recovered their agglutinability (Zlatogoroff 1909, Craster 1914, Taylor and Ahuja 1935).

Koch's observations have been repeatedly confirmed in all parts of the world. In large outbreaks of cholera, the comma bacillus has been found in nearly every case; and the further study of the vibrio has left little doubt in the minds of most observers that it is the specific cause of the disease. It is only fair, however, to point out that not everyone accepts this unitarian view of the origin of cholera. The place of the El Tor vibrio, in particular, has for long given rise to discussion, which the observations of de Moor (1938) in the Celebes outbreak of 1937 have but served to accentuate. In this outbreak de Moor isolated hæmolytic agglutinable vibrios from the patients themselves and from a number of healthy contacts. Van Loghem (1938), who examined de Moor's strains, concluded that they were identical with El Tor vibrios, and being unable to deny their pathogenic rôle concluded that the Celebes outbreak was not true cholera, but a specific enteritis caused by the El Tor bacillus. Otten (1939), however, found that the hæmolytic activity of the Celebes strains was considerably less than that of true El Tor strains, and therefore left the real nature of the Celebes outbreak undetermined. The differentiation of the El Tor from the true cholera vibrio is not always easy, but most recent workers who have given their attention to this problem (see Vassiliadis 1937, Venkatraman, Krishnaswami, and Ramakrishnan 1941) are of the opinion that the El Tor vibrio is not a cause of true cholera.

Bacteriologically, the disease is essentially due to the growth, often in almost pure culture, of cholera vibrios in the intestine. On their autolysis the organisms liberate toxic bodies that have an extremely irritating effect on the intestinal tract, leading to severe and repeated purging, exhaustion, and death.

Experimental Reproduction of the Disease in Animals and Man.—Natural cholera in animals is unknown, but there are certain experimental procedures by which a disease closely resembling cholera can be reproduced in guinea-pigs and rabbits.

Using dogs and rabbits, Nicati and Rietsch (1884) found that the direct injection of comma bacilli into the duodenum was followed by a fatal disease, characterized by the presence of vibrios in large numbers in the small intestine. Koch (1886*b*) confirmed this observation on guinea-pigs, but pointed out that the frequency of a fatal termination depended on the amount of trauma accompanying the injection. He tried to infect the animals by the mouth; and in order to enable the vibrios to pass through the stomach unharmed, he rendered the gastric contents alkaline by the administration of 5 ml. of 5 per cent. sodium carbonate solution. Twenty guinea-pigs treated in this way were shortly afterwards fed with 10 ml. of a broth culture of cholera. Only one died—an animal that had recently aborted. This suggested to Koch that the relaxation of the animal's intestine might have been responsible for the infection. Into his next batch of 35 guinea-pigs, therefore, besides giving the sodium carbonate and the cholera culture, he injected 1 ml. of *Tinct. opii* intraperitoneally to paralyse the gut, and to prolong the stay of the vibrios in the small intestine. The result was that 30 of the animals died, displaying before death weakness of the hind limbs and collapse. At necropsy, the small intestine was deeply injected and filled with a flocculent colourless fluid, containing the vibrios in almost pure culture.

Metchnikoff (1894), working at first with the Massauah bacillus, and later with a true cholera strain, was able to convey the disease to sucking rabbits by rubbing the vibrios on the mother's teats. Diarrhœa usually followed, and about half of the animals died—in 2 to 5 days. What was even more interesting was that if the animals, shortly after they became ill, were put alongside litters of normal rabbits, many of the latter became infected. Sanarelli (1921), from experiments on very young rabbits, concluded that the vibrios were absorbed by the bucco-pharyngeal mucosa, passed through the cervical lymphatic glands, entered the blood stream, and were excreted into the cæcum and colon, whence they ascended the small intestine, and gave rise to the typical lesions of the disease. After the rabbits were 10 days old they could no longer be infected by the mouth. In man, however, tissue invasion appears to be very uncommon.

Adult rabbits can also be infected experimentally, though by a different route. Thomas (1893) found that if they were injected intravenously with living vibrios, most of them died within 36 hours; diarrhœa was present as a rule only in those that lived longer than 24 hours. Post mortem, however, in all the animals there was a creamy, soup-like fluid in the duodenum, and rice-water in the jejunum and ileum, containing vibrios in large numbers. Small ecchymoses of the mucosa were also seen. These findings were confirmed by Issaeff and Kolle (1894), who pointed out that the most typical picture occurred in those rabbits which survived for 3 or 4 days after injection. At the post-mortem examination of these animals, as well as the changes already described, most of the epithelium was found to be detached, so that the internal surface of the small gut was lined by the basement membrane. Isolated patches of epithelium were packed with vibrios. Of 35 rabbits inoculated with doses varying from 1/20 loopful to 9 loopfuls of an 18-hours' agar culture, 27 died.

In man there have been numerous cases of laboratory infection, both in-

tentional and unintentional, resulting from cholera cultures. Koch (1886) recorded the case of a medical man who attended a bacteriological course in Berlin, and developed cholera. Since there was no cholera at the time either in Berlin or the rest of Germany, it is practically certain that he contracted his infection in the laboratory. Dr. Oergel of Hamburg infected himself with the peritoneal exudate of a guinea-pig that had been injected with cholera vibrios; a drop spurted up and entered his mouth. The following day he was ill, and a few days later he died in coma. There was no cholera in Germany at that time. Pfeiffer and Pfuhl (see Kolle 1894) both contracted infection in the laboratory. Pfeiffer, who infected himself at Berlin while making animal experiments with a strain freshly isolated from a cholera case in Hamburg, developed a sharp attack: vibrios were found in his fæces and persisted till the 33rd day of the disease. Agglutinins to *V. choleræ* were demonstrated in his serum. Pfuhl had only a mild attack, vibrios persisting in his fæces for 8 days. Numerous other instances are recorded of similar laboratory infections (Kolle and Schürmann 1912).

Amongst the intentional cases, the best known are those of von Pettenkofer and Emmerich. Doubting the value of Koch's work, both these observers decided to test the effect of the vibrio on themselves. After a preliminary dose of sodium bicarbonate, they drank some water to which a small amount of fresh cholera culture had been added. Von Pettenkofer suffered from diarrhœa only; but his less fortunate companion developed a severe attack of cholera. As well as having diarrhœa with typical rice-water stools, he passed into a profound state of toxæmia with suppression of urine and the *vox cholerica*. Many attempts to produce artificial infection in man have, however, been fruitless. Metchnikoff (1893) carried out a number of experiments on himself and others, sometimes with positive, but more often with negative results. So far as the ætiology of the disease is concerned, negative experiments are, as Koch pointed out, of little value. We do not know all the factors that are necessary for the reproduction of the disease, and quite often the conditions in individual experiments must be unsuitable. The experiments that Nature provides on a large scale are far more convincing.

The Toxins of Vibrio Choleræ.—These have already been described in Chapter 22.

Epidemiology.

In India cholera is most prevalent during the hot weather. Thus in Lower Bengal the maximum incidence is reached from February to May; in the Punjab from May to October (Rogers 1911). The disease is commoner in men than in women. The case mortality is lowest in the 11–20 age group, and increases with age; in the figures cited by Rogers the case mortality in patients between 11 and 20 years of age was 51·3 per cent., in those over 50 years of age it was 73·7 per cent. The effect of atmospheric conditions seems to vary in different parts of India; those who are interested will do well to study the very careful statistical analyses made by Russell and Sundararajan (1928). The disease in India occurs with a certain periodicity, and by calculations based on the relevant data it is said to be possible to predict an epidemic 2 or 3 months ahead of its occurrence (Russell and Sundararajan 1926–27).

The true home of cholera is the delta of the Ganges. Here the disease has occurred year after year for centuries. Previous to 1817 it had apparently never spread widely from this area, but since that year it has manifested an increasing

disposition to invade not only other parts of India, but almost the whole world. The disease now recurs so constantly in certain areas, such as the West Indies, Southern China, the Philippines, Persia, Arabia, and South-East Russia, that these must be regarded as endemic foci. In other areas it usually dies out, though it may be reimplanted from time to time. In India alone the number of deaths from cholera during the 10 years 1898–1907 was 370,000 or 1·64 per 1,000 of the population. It is the low-lying alluvial tracts and the seaports that are most invaded; on high land the disease spreads less readily.

Mode of Spread.—There are many ways in which infection can be transmitted from the sick to the healthy person. A study of the epidemiology of cholera indicates, however, that outbreaks can be divided into those dependent on (1) water-borne infection, and (2) case or carrier infection.

The classical example of a *water-borne* outbreak is the Hamburg epidemic of 1892. Hamburg, and two of its suburbs—Altona and Wandsbeck—were provided each with a different water supply. Hamburg drew its water from the river Elbe at a point above the city, and did not filter it. Altona drew its water from the Elbe below Hamburg, after the fluid refuse and fæces of nearly 800,000 people had been poured into it, but it took the precaution to instal a highly efficient sand-filtration plant. Wandsbeck received its supply from a relatively non-polluted lake, and likewise filtered it. On August 16, 1892, a case of cholera was reported in Hamburg. Others occurred in rapid succession, till by the end of the month there were about 1,000 fresh cases a day. When the epidemic came to an end, on October 23, the figures were: Cases 18,000; deaths 8,200. The incidence of cholera in Altona and Wandsbeck was in comparison very low. Altona reported 516 cases, but there is reason to believe that most of these acquired their infection in Hamburg. On the Hamburg-Altona frontier the line of demarcation between the two towns was very irregular, and there was much overlapping of the water supplies. It was observed that in the same street the houses that were supplied with the Hamburg water were invaded by cholera, whereas those supplied with the Altona water were spared. The Elbe was probably infected originally from the excreta of cholera patients on board the numerous barges anchoring opposite the Hamburg water intake. During the outbreak, cholera vibrios were isolated from the river not far below the mouth of the main Hamburg sewer (Koch 1894). There is here a perfectly clear demonstration of the ability of water to convey the cholera vibrio, and of the efficacy of sand-filtration in protecting a town against a highly polluted source of water. Numerous other outbreaks are on record in which the water supply has become infected and has led to the development of cholera.

Epidemics originating in this way are generally explosive; the ascending limb of the incidence curve rises very steeply; the epidemic soon reaches its maximum, and with the cleansing of the water begins to fall. The decline is, however, less steep than the ascent, probably because a number of contact infections occur that are not directly dependent on the water-borne infection at all, and therefore continue to arise even after the water is clean again.

The second method of infection—*case or carrier infection*—is the one by which the disease is spread from place to place, and attains its widespread distribution. Infected material is conveyed from the sick to the healthy person, either by water, food, or infected linen. Milk, raw fruits and vegetables, and other uncooked food are all able to serve as media for the transference of the vibrio. Clothing, especially

linen, if kept moist, can retain its infectivity for several days or even weeks. Numerous experiments have been made to test the survival time of the cholera vibrio under natural conditions.

Greig (1913–14*b*) in India stored the rice-water stools of 94 patients in a dark cupboard at room temperature, taking care to prevent evaporation. The average life of the vibrio was 7 to 9 days in the cooler weather, and 1 to 2 days in the hot weather. The longest survival time was 17 days. Gamaleïa (1893) found that on linen strips kept moist in a water-saturated atmosphere the vibrios lived for about 5 weeks; when the strips were dried in a desiccator, they died in 17 hours. Dried on silk threads the vibrios rarely live for more than a few hours, but sometimes they may survive for 3 or 4 days (Kitasato 1889). Berckholz (1889), however, found that on threads dried in air they might live for as long as 30 days. In water *V. cholerae* remains viable for a variable time. Houston (1909), who added cultures of the vibrio to raw river water, found that 99·9 per cent. of the organisms were dead in a week; none survived longer than 2 weeks. Haffkine and Simpson (1895) in Calcutta brought evidence to show that the survival time of the vibrio in water was less than 5 weeks. Some natural waters, such as the Jumna and the Ganges (Hankin 1896), appear to be unfavourable to its survival. Probably much depends on the purity of the water. In spring water the vibrios lived for 30 days, in Berlin sewer water for 6 to 7 days, and in cesspool water for less than 24 hours (Koch 1886*b*).

Speaking generally, we may say that heat and desiccation are rapidly destructive; but that under suitable conditions of moisture and temperature the cholera vibrio may survive outside the body for a considerable time.

Patients who have recovered from cholera may continue to excrete the vibrio —often very irregularly—for some weeks. As a rule about 90 per cent. become free from infection within a fortnight, and 99 per cent. in a month. But occasionally the vibrios may persist for 3 to 4 months, or even—as in one recorded case —for a year. It is not only convalescents, however, who are infective; healthy persons who have been in contact with cholera cases may become infected and excrete the vibrios without manifesting any sign of the disease. Sometimes cholera eventually develops in these healthy carriers—possibly owing to an alimentary indiscretion—and if this occurs some time after their contact with cholera patients it may be very puzzling to trace the source of their infection. Munson (1915), for example, discovered three healthy carriers in a prison in Manila. These were isolated and examined daily. Two of them, after having been carriers for 16 and 17 days respectively, developed cholera, and the third developed it after 18 days and died in 8 hours. As Munson points out, this man might have travelled half-way round the world scattering his infection broadcast during his 18-day period as a carrier, and died of true cholera in a place many thousands of miles from any other source of infection. These cases are probably exceptional, but there is evidence to suggest that many persons do not develop the disease clinically for some hours—24 or more—after the vibrios are demonstrable in the fæces (Crendiropoulo 1912). It is probable that the cholera vibrio often survives in the gall-bladder, and from there is excreted into the intestine. Greig (1913), who examined the bile of 271 fatal cases of cholera, isolated the specific vibrio from 80 of these, and found evidence of cholecystitis in 12 of the 80 positive cases. Similar results are reported by Schobl, Kulescha, Hunter and others (see Elkington 1916). Sometimes it is excreted in the urine (Greig 1913–14*a*).

The spread of contact infection may be aided to some extent by flies. Cholera vibrios have been isolated from flies taken in infected houses, from flies caught in a post-mortem room in which cholera corpses had been examined, and from the

feet of flies caught 17 hours after their experimental contamination (Elkington 1916).

Contact infection is responsible for the usual *chain-spread* of cholera. Cases occur in different localities, often widely separated from each other, exhibiting a regular sequence of infection. With the rapidity of modern transport it is often very difficult to ascertain all the links in a given chain. When it is remembered that infection may be carried and transmitted by apparently healthy persons, the magnitude of this difficulty will be appreciated. An excellent example of this chain-spread is afforded by the Hamburg epidemic of 1892. This, as we have already stated, was due to an infected water supply; but from Hamburg the disease was carried by infected persons to nearly 300 places in Germany and other countries.

Often the presence of a carrier in a community is rendered probable by the development at intervals of clinical cholera cases for which no obvious source of infection is recognizable. The production of these "cholera nests," as they are called, is particularly frequent in the East, where the sanitary conditions are poor.

The two methods of infection described may be, and frequently are, combined. In the suburbs of Calcutta, for example, the tanks, which supply a large proportion of the native population with water, are freely open to pollution from cholera cases, so that whenever a tank belonging to a given household becomes contaminated, a small outbreak may result. Since the water in these tanks is used not only for drinking, but for washing, bathing, and sewage disposal, it is not surprising that they are frequently responsible for the conveyance of infection.

Diagnosis.

The bacteriological diagnosis of cholera may be very easy, or remarkably difficult. Here we can indicate only the outline of the methods to be employed. (For further details see Koch 1886*a*, 1894, Ellermann 1904, Crendiropoulo 1912, Craster 1913*a*, *b*.)

The fæces or intestinal contents should be examined microscopically. A flake of mucus, for preference, should be spread on a slide and stained with dilute carbol-fuchsin. If comma bacilli are present in pure or almost pure culture—especially if they present the typical fish-in-stream appearance—a provisional diagnosis of cholera can be made directly. By this means alone Koch (1894) was able to diagnose about 50 per cent. of the specimens sent for examination to the Institute for Infectious Diseases at Berlin. If, however, other bacilli are present, it is advisable to suspend judgment till further examination has been made.

The fæces should be transported to the laboratory as rapidly as possible. If more than a few hours are likely to elapse before their reception, they may be put into a preserving solution such as the borate saline mixture described by Venkatraman and Ramakrishnan (1941). On arrival at the laboratory they should be seeded at once into a tube of ordinary peptone water (1 per cent. peptone, 0·5 per cent. NaCl). In this medium, cholera vibrios are able to grow more rapidly than other intestinal bacilli. Multiplication occurs chiefly at the surface, where a thin pellicle forms in the course of a few hours. After 6 to 12 hours' incubation at 37° C., a loopful taken from the surface should be filmed, and if vibrios are present, a fresh tube of peptone water should be seeded and an agar plate streaked with a loopful taken from the surface of the culture. Alternatively a selective medium, such as Dieudonné's (see Vedder and van Dam 1932), the phenolphthalein

starch medium described by Yen (1932-33), or the sucrose mannitol sulphate bismuth alcohol phenol red agar medium of Wilson and Reilly (1940) may be used. After 12 to 18 hours' incubation, the peptone water culture should be tested by the addition of pure sulphuric acid for the cholera-red reaction. The colonies on the agar plate should be examined after 12 hours, and mixed. If they consist of vibrios, 1·5 mgm. (about a loopful) of culture should be rubbed up in 1 ml. of broth and injected intraperitoneally into a guinea-pig. At the same time 2 or 3 tubes of broth should be seeded with single colonies, and incubated at 37° C. After 3 days they should be tested for haemolysin production by the addition of 1 ml. of culture to an equal quantity of a 5 per cent. suspension of washed goat or sheep red blood cells; this mixture should be incubated for 2 hours at 37° C. and kept overnight in the cold before reading. A suspension of colonies on the agar plate should be made in 0·2 per cent. formol, and tested against an agglutinating serum containing the specific cholera O (sub-group I) antibody (see Gardiner and Venkatraman, 1935); living vibrios may be used instead, but not boiled or chloroformed suspensions. For practical purposes the isolation of a non-haemolytic vibrio with the specific O antigen of sub-group I may be regarded as diagnostic of cholera. Vibrios having the O antigen of sub-group I, but haemolysing sheep or goat red cells, belong to the El Tor group. Not too much weight, however, should be placed on the hæmolytic or non-hæmolytic activity of the organism, since the ability to produce an active hæmolysin seems to depend on a number of factors which are not always easy to control (see Chapter 22).

If the cholera vibrios are scanty, and particularly if they are being sought for in water, it is advisable to incubate the material in a sulphite bismuth enriching fluid medium such as that described by Read (1939) or Wilson and Reilly (1940) before plating out. A higher proportion of successful isolations may be expected by such a method (Seal 1939). The final identification of the organism should be made by the absorption of agglutinins test and by Pfeiffer's (1895) reaction. For this 4 guinea-pigs are required. (1) 1 loopful of an 18 hours' agar culture at 37° C., suspended in 1 ml. of broth, is mixed with 0·001 ml. of a high-titre cholera antiserum and injected intraperitoneally. (2) The same inoculum, with 0·002 ml. of antiserum. (3) The same inoculum, with 0·01 ml. of normal serum. (4) 1 loopful of culture alone is injected. The 3rd and 4th animals act as controls. Immediately after injection, and 20, 40 and 60 minutes later, a drop of peritoneal exudate is removed by a fine Pasteur pipette from each of the four animals, and examined in a hanging-drop preparation. If the reaction is positive, in animals 1 and 2 the vibrios will lose their motility, swell up, and undergo granular degeneration; in animals 3 and 4 the drop will be seething with actively motile, comma-shaped vibrios. The reaction may alternatively be carried out *in vitro*. Pfeiffer's reaction is highly specific. If a mixture of *V. choleræ*, and *V. metchnikovi*, for example, is added to an immune anti-cholera serum and injected into a guinea-pig, only the cholera vibrios undergo lysis; the others are unaffected, multiply, and kill the animal.

During an epidemic of cholera the bacteriological diagnosis can usually be made by simple microscopical and cultural examination, supplemented, if necessary, by the cholera-red and the agglutination reaction. But in non-epidemic times, or at the beginning of an epidemic, especially in a country usually free from cholera, the diagnosis should never be made till all the tests described have been performed and found positive.

The identification of vibrios from carriers or cholera contacts, and from non-human sources such as water or milk, is often very difficult, and has to be performed with the utmost care. Vibrios are often found under these conditions (Dunbar 1893, Kutscher 1893, 1895, Gotschlich 1895, 1906, Haffkine and Simpson 1895, Neufeld and Haendel 1907, Ruffer 1907, Zlatogoroff 1909, Crendiropoulo 1912, Craster 1913*a*, *b*, 1914, Jermoljewa 1926) that bear an extremely close resemblance to the cholera vibrio, and can be differentiated from it only by intensive study. Even in cholera stools, antigenically atypical forms, such as those described by Chen (1932–33), Yang and White (1934), Aoki and Oshiro (1934), and White (1935), are often found. In the examination of such vibrios, attempts should be made by repeated subculture and intraperitoneal inoculation of mice or guinea-pigs to bring about a change to the typical antigenic form. Most non-cholera vibrios are harmless to guinea-pigs, but the pathogenicity test cannot be relied on exclusively.

In the examination of suspected convalescents, besides looking for the vibrio in the fæces, it is well to test the serum for agglutinins and bactericidins. When a large-scale investigation has to be carried out in the search for carriers, a rectal swab should be taken from each person and inoculated into peptone water. Subcultures and plates are made from this after 6 to 9 hours' incubation. Using this method Craster (1913*b*) at the Quarantine Station, New York, examined nearly 27,000 immigrants in 4 months, and identified 31 as carriers.

Prophylaxis and Treatment.

The prevention of cholera is similar to that of typhoid. Owing to the serious nature of the disease stringent precautions have been taken, particularly at seaports, to prevent its introduction into countries usually free from cholera and its subsequent dissemination. (For an account of these see Elkington 1916.)

Vaccination.—Ferran (1885) in Spain was the first to attempt vaccination against cholera. He injected small doses up to about 0·5 ml. of a living broth culture subcutaneously; a severe local and general reaction followed. The results were not satisfactory; and the work was suppressed by the Government.

Haffkine, a pupil of Pasteur's, then took up the problem. He (1892) prepared two living vaccines: (1) consisting of vibrios whose virulence had been attenuated by frequent cultivation in a constantly aerated atmosphere; (2) consisting of vibrios whose virulence had been exalted by 20 to 30 passages through the peritoneal cavity of guinea-pigs. These vaccines were used on a fairly large scale in India; sometimes only the first vaccine was given, sometimes both. The figures have been published by Haffkine (1895*a*, *b*, 1913), and critically discussed by Kolle (1896*b*). It is impossible here to give the results in tabular form. The injections were made on numerous tea estates, in regiments, gaols, and families. The numbers of inoculated and uninoculated were often unequal; the two sets were unevenly exposed to risk of infection; in some instances the inoculation was performed during the progress of the epidemic; in others the disease did not break out for a year or more after inoculation; and the cases that did occur were too few to afford a correct idea of the comparative immunity of the two groups. Haffkine's statistics have been carefully examined by Greenwood and Yule (1915), who point out the variability of the results of inoculations performed in different areas. They conclude, however, that certain of the results establish a presumption in favour of the value of Haffkine's inoculation.

Later (1911, 1913), Haffkine abandoned his living vaccines, and recommended

the use of his vaccine ii, killed by heat at 50° C. for a few minutes, and preserved with 0·5 per cent. phenol. Kolle (1896*a*) was the first to introduce the killed vaccine. By experiments on himself and his colleagues, he showed that the injection of 1 10 to 1 5 of a 24-hours' agar culture, killed by chloroform vapour or heat, stimulated the production of specific bactericidal antibodies. His vaccine has been employed on a fairly large scale by Murata (1904) in Japan, and by Savas (1914) in Greece. The significance of Murata's results is very doubtful, since only one inoculation was given, and there is some doubt as to the homogeneity of his statistics (see Greenwood and Yule 1915). Savas employed anti-cholera vaccination in the Grecian Army during the second Balkan War. As the greater part of the inoculations were made during the progress of the cholera epidemic, it follows that the exposure to risk of infection was different amongst the inoculated and the uninoculated. For this reason statistical analysis of most of Savas' figures is not likely to afford much information as to the value of vaccination. An exception must be made for the Sanitary Corps, nearly every member of which received two inoculations before the disease broke out. A comparison made between the incidence of cholera among the members of the Sanitary Corps and among the combatants is recorded in Table 120 (taken from Greenwood and Yule 1915).

TABLE 120

	Not Attacked.	Attacked.	Total.
Sanitary Corps	2,884	13	2,897
Combatants	112,613	2,192	114,805
Total	115,497	2,205	117,702

$\chi^2 = 32{\cdot}79$. P = less than 0·0001.

The value of χ^2 is high; and the probability that the difference in the attack rates between the two groups is attributable to chance is much less than 1 in 10,000 (see p. 1551). Greenwood and Yule (1915) conclude from these results that "anti-cholera inoculation . . . is a prophylactic step of importance, although an exact statistical measure of the degree of relative immunity conferred cannot be provided."

Kolle's vaccine—a 24-hours' agar culture killed by heat at 55° C. for 1 hour, and preserved with 0·5 per cent. phenol—has now replaced all others. The standardization and dosage of this vaccine vary in different parts of the world. Two doses, each of 2,000 million organisms, at an interval of at least a week, should be given. If only one dose is practicable, 4,000 to 8,000 million organisms may be recommended (Dzen and Yu 1936). According to Griffiths (1944) antibodies, demonstrable by a mouse protection test, appear in the serum one week after vaccination.

Bacteriophage Treatment.—Administration of bacteriophage is now being tried both prophylactically and therapeutically in the treatment of cholera. The data so far collected are scanty and refer to native populations, amongst whom the collection of exact records presents peculiar difficulties (see Morison 1932, Asheshov *et al.* 1930, Asheshov 1933). What is usually regarded as the ideal method—

that of treating alternate cases—is not only generally impossible but may be undesirable, since under primitive conditions of sanitation rapid transference of the bacteriophage from treated to untreated persons is likely to occur. Comparisons have usually to be made (1) between a group of treated and another of untreated patients in any given epidemic; unless the two groups are practically identical in age, sex, time of exposure, risk of exposure, and other relevant factors, such a comparison may yield very misleading results; (2) between the mortality in treated cases in one epidemic and that in untreated cases in a previous epidemic; since the case mortality in different epidemics is subject to considerable variation altogether apart from any active interference on the part of man, this method is likewise unsatisfactory. For the moment, therefore, we must reserve our judgment on the value of bacteriophage treatment. We may note, however, that in cholera the bacteriophage ought to be acting under probably more favourable conditions than in any other disease. The organisms are multiplying in the fluid contents of the intestine, not in the intestinal wall, as in dysentery and enteric fever, where the action of the bacteriophage is likely to be nullified by the tissues. In view of the favourable light in which this method is regarded by many clinicians, it seems probable that it does have some beneficial effect on the course of the disease, but in this, as in other similar problems, we must await the collection of adequate statistical material before coming to a definite decision.

Serum Therapy.—Antisera to cholera are readily prepared by the injection of goats or horses with dead, followed by living, vibrios. The resultant serum has a marked prophylactic effect when tested by the intraperitoneal method in guinea-pigs, but unfortunately its therapeutic powers are low. Injected more than an hour or so after the vibrios, it fails to save the animal's life (Pfeiffer 1894). This is doubtless because the antibodies in the serum are chiefly bactericidal, and are unable to neutralize the toxins liberated by the disintegration of the vibrios. For the treatment of cholera cases, a serum is required that has a high anti-endotoxic titre. Several attempts have been made to produce such a serum. Macfadyen (1906) used an extract of young agar cultures ground up in liquid air for immunizing rabbits and goats. Tested on guinea-pigs 0·5 ml. of the rabbit's serum, after inoculation of toxin, protected against 8 lethal doses, and 0·002 ml. of the goat's serum protected against 3 lethal doses. Schurupow (1909) immunized horses with an alkaline extract of 2-days' cholera cultures, and apparently succeeded in obtaining an anti-endotoxic serum. Unfortunately these sera have not been used on a large scale in practice, and it is impossible, in spite of the favourable reports (Savas 1914) that have been made on them, to estimate their value in treatment.

Chemotherapy.—The information so far available on the value of the sulphonamide group of drugs in the treatment of cholera is promising. Hopeful results have been reported by Chopra, de Monte, Gupta and Chatterji (1941) and by Huang (1944) from the use of sulphaguanidine. During an outbreak in Kweilin, Huang gave adult patients an initial dose of 3 gm., followed by six 1 gm. doses at 2-hourly intervals, and 1 gm. doses every 4 hours for one to two days. The patients are said to have improved within 3–4 hours after taking the drug; the stools became negative in 8 hours. Of 22 patients treated, only one died. Previously, patients treated in Kweilin by the routine method of hypertonic saline, kaolin, potassium permanganate and so on had a case mortality of 26 per cent.

CHAPTER 64

MENINGITIS

Introductory

Meningitis is an inflammatory affection of the membranes surrounding the brain and spinal cord, which occurs sometimes as a primary disease, and sometimes secondarily to disease of some other part of the body.

Prior to the advent of bacteriology the tuberculous form was recognized, the cerebrospinal form when it occurred in epidemics, and the post-basic form in children.

The discovery of the tubercle bacillus by Koch in 1882 provided a bacteriological means of differentiating the tuberculous from other forms of meningitis. Pneumococci were shown by Fraenkel (1886), Foà and Bordoni-Uffreduzzi (1886), and others to be responsible for the meningitis which occasionally complicates lobar pneumonia. In 1887 Weichselbaum of Vienna published his classical paper on the finding of a Gram-negative diplococcus in six cases of acute cerebrospinal meningitis; this organism he named the *Diplococcus intracellularis meningitidis*. The same year his work was confirmed by Goldschmidt (1887) and by Edler (1884–88). Jaeger (1895), in describing the differences between the pneumococcus and the meningococcus, assigned to the latter characters which it does not possess, and numerous papers were published during the following 10 years dealing with the differences between his description and that of Weichselbaum (Scherer 1895, von Hibler 1896, Heubner 1896, Kiefer 1896, Kister 1896, Still 1898, Councilman *et al.* 1898, Faber 1900, Jaeger 1903*a*, *b*, Albrecht and Ghon 1901, 1902, 1903). The correctness of Weichselbaum's observations was finally established by the extensive studies of von Lingelsheim (1905*a*, *b*) during an epidemic of cerebrospinal fever in 1904–5. Since that date the *Diplococcus intracellularis meningitidis* of Weichselbaum, or, as it is now called, *Neisseria meningitidis*, has been recognized as the causative organism of the disease. Still showed in 1898 that the post-basic meningitis of children is due to a Gram-negative diplococcus apparently identical with Weichselbaum's, and subsequent work has shown that the two organisms are the same.

Other forms of meningitis will be dealt with at the end of the present chapter

Cerebrospinal Meningitis

This is an infectious disease characterized by inflammation of the meninges, particularly at the base of the brain. It may be acute or chronic, and may occur sporadically or epidemically. The causative agent is the meningococcus. The disease can be reproduced experimentally by the intrathecal inoculation of virulent meningococci into monkeys and rabbits (see Chapter 23). There is reason to

believe that the pathological manifestations are due mainly to the presence of endotoxic substances, which are contained in the bacterial cells and are liberated when these undergo autolysis.

Epidemiology.

I. History and Incidence.—The first definite knowledge that we have of cerebro-spinal fever is due to Vieusseux, who in 1805 described an outbreak of the disease at Geneva. In the following year it appeared in Medfield, Massachusetts, and during 1806-07 it attacked the Prussian Army. Since then it has invaded most countries in the world, rising at one time to epidemic proportions, subsiding at other times to remain dormant for long periods, but inevitably reappearing in outbreaks of greater or less severity. The disease has, in fact, shown a gradual increase, both in its geographical range and in the number of persons it has attacked. Thus, according to Hirsch (1886) from 1805 to 1830 the disease was most prevalent in the United States; from 1837 to 1850 France was attacked most severely; from 1854 to 1874 epidemics occurred both in Europe and in America, and from 1875 down to the present time not only these two continents but Asia, Africa, and Australia have been invaded (Low 1916).

The first undoubted case reported in Great Britain occurred in 1830. From that date the disease remained endemic in this country, giving rise to occasional small outbursts. Our knowledge of the disease previous to 1912, the year in which compulsory notification was introduced, is largely furnished by the death returns; these record a gradual rise from 1900, when 9 deaths were recorded in England and Wales, to 1911, when 134 were recorded. In 1907 there was an outbreak of epidemic proportions in Scotland and Ireland; Edinburgh had 206 cases with 135 deaths, Glasgow 998 cases with 715 deaths, and Belfast 623 cases with 495 deaths.

The first large epidemic recorded in England occurred in 1915. It began late in 1914 amongst the Canadian Expeditionary Force (Reece 1916) quartered on Salisbury Plain, and rapidly spread, involving both the civil and the military population. The following figures are instructive (Rolleston 1919) (Table 121).

TABLE 121

ENGLAND AND WALES

	Cases.	Deaths.
1912	272	142
1913	304	163
1914	300	206
1915	2,343	1,521
1916	1,278	838
1917	1,385	906

During the war of 1914–18 the British Expeditionary Force in France was attacked with some severity; the French Army suffered less, and the German Army hardly at all.

New York suffered severely in 1904–05. In the latter year there were 2,755 cases with 2,026 deaths (Flexner 1907*a*). Extensive outbreaks were reported in France in 1909–10, and in Texas in 1912. More recently the disease has increased

in some countries. There was a particularly severe outbreak in the United States in 1928–30 (see Hedrich 1931). In England and Wales the incidence rose from 300 cases and 284 deaths in 1923, to 2,152 cases and 1,440 deaths in 1931.

The disease attacks particularly children and adolescents. Compton (1918) finds that the most susceptible age is 0 to 5 years; the susceptibility is slightly less from 5 to 10, distinctly less from 10 to 15, and for the remainder of life it remains fairly low—at about 1/5 of that of the 0 to 5 age period. In the Danzig epidemic of 1865, 93 per cent. were under 5 years of age. The disease is unusual, however, in the first 3 months of life. It is somewhat commoner amongst males, but this appears to be related more to increased opportunity for infection than to any special sex predisposition. Miners and soldiers are the two occupational classes on which the disease falls most heavily. The seasonal incidence is very marked, the greater proportion of cases occurring in winter and spring: during 1915 and 1916 in England, 77 per cent. of the cases were in the first six months of the year. Much has been written about weather conditions. A low temperature, a cold wind, and increased humidity of the atmosphere appear to be predisposing agents (Dopter 1921), but it seems probable that these act mainly by leading to overcrowding indoors. Fatigue exerts a powerful influence; it is the recruits, unaccustomed to the rigours of military life, who furnish the greatest number of cases in the Army. Dopter tells an impressive story of a party of recruits who made a long, fatiguing march to join their regiment at Versailles. On reaching their destination cerebrospinal fever broke out, and of a total strength of 153 men no fewer than 79 developed the disease.

II. Mode of Spread of the Disease.—The disease is endemic in large towns, from which, at least in the post-basic form, it rarely disappears. Every winter and spring a few fresh cases occur—sporadic cases affecting children, less frequently young adults—which appear at widely separated points having no apparent connection with each other. In villages the endemic state is practically unknown.

Every now and then an epidemic breaks out. As a rule it starts insidiously by the occurrence of one or two cases at intervals of a week or more; it then begins to advance by the formation of small multiple foci in families, schools, barracks, or gaols. Often it works itself out in one focus before passing on to another. Thus, at Strassburg (Dopter 1921) in 1840 the 7th line regiment was attacked in October; three months later it spread to the 69th regiment, of which two companies were quartered with a part of the 7th. In January the 29th line regiment and the 11th artillery were attacked; in February the 34th line regiment and the 1st artillery; and in March, 6 months after the commencement of the outbreak, it invaded the pontonniers.

In a town the cases are not aggregated together, but occur widely scattered, as if there were no causal relationship between them. Thus in Hamburg between 1880 and 1885 the 180 cases of cerebrospinal fever that occurred were distributed over 131 streets.

The spread of the epidemic is irregular and capricious; often groups, which from their situation appear certain to be attacked, escape, whereas others, situated remotely from the primary focus, are attacked. Similarly with regard to time; the successive outbreaks of an epidemic are irregular; there are paroxysms of intensity followed by remissions or intermissions. The decline of the epidemic takes place slowly, fewer and fewer foci remaining, till finally the endemic state is regained (Dopter 1921).

It is remarkable what a predilection the disease has for the military population; frequently garrisons have been attacked without a single case amongst the neighbouring civilians. Of 75 epidemics in France, collected by Hirsch (1886), 39 were confined to the troops. In Germany the miners of Westphalia and Silesia have suffered severely. In India it is the gaols that appear to have furnished most of the cases.

Two of the most striking features of a cerebrospinal fever epidemic are the low morbidity and the high case fatality. Dopter (1921) says that the morbidity varies between 0·01 and 0·3 per cent. of the population at risk, though occasionally it may rise higher. The case mortality is generally about 70 per cent.; it may be as low as 37 per cent., or as high as 90 per cent. During the years 1920–36 the average case-mortality rate in 22 cities of the United States was 51·2 per cent. (Walsh 1938).

Long before the discovery of the causal organism, it had been noticed that overcrowding favoured the development of the disease. The reason for this was not known. At a post-mortem examination of a case of cerebrospinal fever, Weigert noticed the presence of a purulent rhinitis, and on the basis of this observation von Strumpell suggested that the nasopharynx might serve as a portal of entry for the infective material. Weichselbaum (1887) in his original paper likewise mentioned that one of his cases had a purulent sinusitis, and expressed the opinion that the organisms might find their way to the meninges *via* the nose. While working with meningococci Kiefer (1896) developed a purulent right-sided rhinitis from which he cultivated Weichselbaum's diplococcus; he did not develop meningitis. During the next few years a number of workers claimed to have isolated the organism from the nose, not only of patients but of healthy contacts. Further work rendered it clear that not only were meningococci frequently present in the nasopharynx of patients suffering from cerebrospinal fever—about 60 per cent of cases in the first week of the disease—but also in the nasopharynx of contacts and even of non-contacts (Albrecht and Ghon 1901, von Lingelsheim 1905*a*, Kutscher 1906, Ostermann 1906). It became clear therefore that the meningococcus was able to vegetate in the nasopharynx—frequently without giving rise to meningitis—and that it could be transmitted from patients to healthy persons in the vicinity.

Certain observers, notably Dopter (1921), have come to the conclusion that the real disease to which the meningococcus gives rise is rhinopharyngitis; the meningitis which occasionally develops is to be regarded, not as the main disease, but as a complication, in much the same way as nephritis is often grafted on scarlatina or paralysis on diphtheria. Actual rhinopharyngitis does not appear to be a common sequel to meningococcal invasion, and it is probably more accurate to speak of this invasion as a "carrier epidemic." There is some evidence, however, that the meningococcus does not act as a pure commensal, because antibodies are sometimes formed as a result of its presence in the nasopharynx (Rake 1935*a*).

During the war of 1914–18 observations of much interest were made on the carrier rate. By swabbing large numbers of the military population in camps and depots, it was found that previous to an outbreak of cerebrospinal fever the proportion of carriers of the meningococcus increased steadily. The normal carrier rate amongst troops was recorded as 2–4 per cent., but preceding an epidemic, it rose till it reached 20–30 per cent. Soon after it had passed the 20 per cent. limit,

isolated cases of meningitis began to appear, and as the epidemic gained foothold the carrier rate likewise rose, sometimes to as high as 88 per cent.

Investigating the cause of this "warning rise" in the carrier rate, Glover (1920) was led to suspect a relationship between it and overcrowding in the sleeping huts. These huts were at the best poorly ventilated (Eagleton 1919–20), and during the stress of war the mobilization standard had been overstepped, so that beds, instead of being separated by 1 ft. 4 in., were practically touching each other. Glover (1920) noticed that the carriers in a given hut tended to be aggregated together; three Type II carriers were in adjacent beds, two Type I carriers, and so on. This pointed strongly to the direct transmission of the meningococcus from one man to another sleeping in the next bed. Finding that the spraying capacity during normal sleep was not more than about 3 ft., Glover tried the effect of spacing out the beds in the hope that the infection would be diminished. The results obtained seemed to be in accordance with expectation. The effect of the distance between the beds was not confined to the carrier rate. At Caterham depot, where there was severe overcrowding, an outbreak of cerebrospinal fever had occurred during each winter of the war, but subsequently to the adoption of the spacing-out policy in 1917–18, not a single case occurred.

Because of the far-reaching conclusions on the relation between overcrowding and the carrier rate, and the importance of detecting the "warning rise," Glover's work has received a great deal of attention.

In the Detroit epidemic of 1928–29, Norton and Baisley (1931) found no correlation between the degree of overcrowding in the home and the contact carrier rate. During the outbreak of 1931 at Aldershot, Armstrong and his colleagues (1931), from a study of the position of carriers in dormitory barrack rooms, were unable to obtain any evidence that infection occurred mainly at night. The carriers were scattered quite irregularly without any particular relation to the position of the beds. Our own nasopharyngeal surveys of the civilian population carried out before the second world war have shown us that the carrier rate in institutions may be as high as 20 per cent. and over, without any outbreak of cerebrospinal fever occurring. Rake (1934) has made the same observation. Perhaps the most striking figures, however, are afforded by Dudley and Brennan (1934). Working at the Chatham naval hospital, they found that between January, 1932, and March, 1933, there were 11 cases of cerebrospinal meningitis with a carrier rate of about 13 per cent. During the period March, 1933, to May, 1934, the carrier rate was 54 per cent., yet not a single case of meningitis occurred. During the same period at the Royal Naval Hospital, Portsmouth, there were 6 cases of meningitis with a carrier rate of only 5 per cent. Analysis of the distribution of carriers at Chatham showed no constant relationship between the density of the population and the carrier rate. The senior ratings with the most spacious sleeping accommodation had as high a carrier rate—60 per cent.—as the recruits with the worst sleeping quarters. Phair, Schoenbach and Root (1944) carried out a survey at an army camp in which cerebrospinal fever was prevalent. There were no cases, however, in the unit they examined. A group of 99 men was swabbed 28 times in 68 days; no fewer than 91 of these men were found on one or more occasions to be harbouring meningococci in the nasopharynx. The average carrier rate was 41 per cent.

These observations lend no support to the suggestion that there is a direct relationship between the carrier rate and the incidence of cerebrospinal fever.

That Glover's observations were correct, no one has questioned; but it may be doubted whether Glover was justified in attaching to them a general rather than a local significance. It is reasonable to suppose that overcrowding must increase the frequency of exchange of nasopharyngeal flora. Whether, however, this neces-

sarily results in a high carrier rate, and if so to what extent overcrowding favours the development of cerebrospinal meningitis, it is at present impossible to say. On the whole it seems probable that the extent of disease depends on the virulence of the invading organism as much as on its distribution. Judged by the mouse test, there is a considerable variation in the virulence of different strains of meningococci isolated from the human body (Cohen 1936). Group I strains, which are responsible for most epidemics, tend to be more antigenically homogeneous and more virulent than Group II strains, which predominate in inter-epidemic periods; and even among Group I strains differences in antigenic structure and in virulence can often be established (see Branham 1940*a*). We are forced, in fact, to much the same conclusion as Griffith in his study of scarlet fever (Chapter 66), namely that whether in an invaded susceptible community the disease becomes epidemic or not is determined largely by the characters of the infecting strain.

Routes of Infection.—There is now no doubt that the meningococcus gains access to the body *via* the nasopharynx. Several early observers claimed to have found the organism in various parts of the respiratory tract, and it was not long before its predilection for the nasopharynx was demonstrated. It is unusual to find it in the nose itself or in the saliva, where, as Gordon (see Report 1917) showed, the salivary streptococci exert an inimical action on its growth; it may be isolated from the throat, but the most important site is undoubtedly the nasopharynx. It is here that it multiplies, and sometimes sets up a rhinopharyngitis.

Whereas there is now general agreement that the nasopharynx is the portal of entry, it is still uncertain by what route the organism gains access to the meninges. There are two main views: the first, supported by Netter and Debré (1911), postulates the direct transmission of the organism from the nose to the meninges; the second, upheld by several workers in Germany, America and England (Westenhoeffer 1906, Elser and Huntoon 1909, Herrick 1918, Bacslack *et al.* 1918, Rolleston 1919), is that it is carried to the meninges by the blood stream. The available evidence is as follows.

(*a*) Direct Extension from the Nose.—The advocates of this view draw attention to the close relation existing between the subarachnoid space and the nose. Around each of the 15 to 18 branches of the olfactory nerve which pierce the cribriform plate of the ethmoid there is a sheath; between this sheath and the nerve itself there is a space which is in direct communication with the subarachnoid space.

Clark (1929) found that a solution of potassium ferrocyanide and iron ammonium citrate, instilled into a rabbit's nose, reached the surface of the brain within an hour. The distribution of the blue granules indicated that the path followed had been the perineural spaces of the olfactory nerves. Further work showed that material might pass from the nasal to the intracranial cavity by way of the blood vessels piercing the cribriform plate. Fine canaliculi, representing prolongations of the subarachnoid space into the olfactory mucosa, have also been described traversing the cribriform plate, homologous with similar prolongations found in the internal ear and around the optic nerve; but Clark was unable to satisfy himself that these canaliculi had any direct communication with the nasal lymphatic vessels. Methylene blue injected into the subarachnoid space beneath the frontal lobe of a dog colours not only the perineural prolongations, but also the lymphatic plexus of the nasal mucosa. The lymph flow appears to be centrifugal, whereas the flow of fluid (not lymph) in the perineural spaces may, as Clark's observations have shown, be centripetal, and thus carry particulate material from the nose to the brain (see also Findlay and Clarke 1935, Rake 1937*b*).

Another possibility is that the organisms may invade the nasal sinuses, set up a purulent

sinusitis, and reach the skull by the lymphatics, or by direct extension through the bone. Numerous observers have found a sinusitis in cases of cerebrospinal fever, particularly of the sphenoidal sinus. Embleton and Peters (1915) examined three patients who had died of the disease, and found in each a sphenoidal empyema due to the meningococcus. Against this view are the facts that, though not uncommon, sinusitis is by no means constant in cerebrospinal fever, and that in children, in whom the disease is commoner than in any other class, the sphenoidal sinus does not develop before the third year of life. Moreover it is possible that the involvement of the nasal sinuses may be secondary to the meningitis, the organism being carried by the natural flow of the lymph stream to the nose. Flexner (1907*b*) found in monkeys, injected intraspinally, that the organisms might find their way from the meninges to the nasopharynx.

As well as the transethmoidal and the sphenoidal routes, it has been suggested that spread may occur *via* the Eustachian tube to the middle ear and thence to the brain. This seems unlikely because of the rarity of otitis media in cerebrospinal fever, and of the lateness of its development when it does occur.

The advocates of direct lymphatic spread from the nose to the meninges object to the hæmatogenous route of infection on the ground that blood cultures are frequently sterile, that positive results are not more common at the beginning of the disease than during its later stages, and that the arthropathies and visceral lesions which sometimes appear as complications occur fairly late in the course of the disease, suggesting that the blood has become secondarily infected from the meninges; that this may occur in animals has been shown by Flexner (1907*b*), who found meningococci in the blood subsequent to intraspinal injection.

(*b*) THE HÆMATOGENOUS ROUTE.—Meningococci were found in the blood by Salomon in 1902; Jacobitz in 1905 reported two cases; Elser (1905–06) obtained 10 positive blood cultures out of 41—mostly in the first week of the disease; Dieudonné (1906) was successful in 4 cases out of 5. During the war of 1914–18 Baeslack (1918) and his co-workers cultivated the meningococcus 8 times from 22 cases, and Barber and Fleming (see Herrick 1918) 12 times from 15 consecutive cases. Moreover the organism has been cultivated from the petechial spots (Muir 1919), from the swollen periarticular lesions (Still 1898), from the endocardial vegetations, and from other situations clearly infected by the blood stream. Cases of chronic meningococcal septicæmia lasting for months, sometimes with ultimate recovery, are not uncommon (for references see Campbell 1943).

From these records it is clear that an infection of the blood is frequently present. It must be remembered that the meningococcus is not an easy organism to grow, and that if it is present in only small numbers the chances of obtaining it in blood culture are not great. With ordinary care, however, at least 25 per cent. of the blood cultures may be expected to be positive in the first week of the disease.

As well as the finding of the meningococci in the blood, other reasons have been advanced in favour of the hæmatogenous route. Clinical evidence shows that a meningococcal septicæmia may occur without the development of meningitis. Herrick (1918) states that 4 per cent. of patients with septicæmia fail subsequently to develop meningitis. Higher proportions than this have been reported by later workers (see, for example, Dickson *et al.* 1941, Daniels *et al.* 1943).

Westenhoeffer (1906), who at one time favoured the direct method of spread, but who later abandoned this view in favour of the hæmatogenous route, was struck by the presence in two cases of cerebrospinal fever of miliary abscesses in the myocardium and in the renal medulla; by the occurrence of cases of purulo-hæmorrhagic encephalitis; and by the finding of pus around the small arteries of the pia in a brain that otherwise appeared normal—all points suggestive of blood infection.

It is clear that the demonstration of meningococci in the blood cannot be regarded as evidence in favour of the hæmatogenous route, unless it can be shown that the blood is generally infected before the meninges; otherwise it is legitimate to argue that the blood-stream infection is secondary to the meningeal invasion. So far the number of cases

that have been studied with a view to determining the sequence of events is insufficient to enable any definite conclusions to be drawn.

Summing up, it may be said that the most probable sequence of events is as follows: The organisms reach the nasopharynx by air-borne infection; here they may set up a rhinopharyngitis, but more usually appear to give rise to no trouble. In some cases, however, the meningococci gain access to the meninges—whether by direct invasion or *via* the blood stream is not yet known. A meningococcal septicæmia in the absence of meningitis is not uncommon, and in a few instances lesions in other parts of the body develop, generally in the late stage of the disease, such as endocarditis, arthropathies, and renal abscesses. These are probably due to a secondary infection of the blood stream from the meninges.

Diagnosis.

In cerebrospinal meningitis the causative organism is always present in the cerebrospinal fluid; in a considerable proportion of cases it is also present in the nasopharynx. In this latter situation Elser (1905–06) found it in 6 out of 22 patients; Weichselbaum and Ghon (1905) in 18 out of 19 patients (not fully identified); Goodwin and von Sholly (1906) found it in 12 out of 22 patients in the first week of the disease, and in 5 out of 15 in the second week. Von Lingelsheim (1908) found it in 46 out of 49 patients in the early stage of the disease. Gordon (see Report 1920) states that it can always be found in the early stage of the disease, but that its isolation is more difficult later. For diagnostic purposes, therefore, it is essential to perform a lumbar puncture, and desirable to take a nasopharyngeal swab.

Examination of the Spinal Fluid.—The spinal fluid should be withdrawn and divided into three portions, which should be treated as follows:

(1) *Examination of centrifuged deposit for cells and organisms, and of the supernatant fluid for specific precipitinogens.* The fluid is centrifuged, the deposit stained by Gram, and examined microscopically for the presence of the oval Gram-negative diplococci. These vary greatly in numbers; sometimes they are present in every field, but in others they are not found until after a prolonged search; in this respect the picture is very different from that of septic meningitis, in which the pneumococci or streptococci are present in large numbers, and can be found without difficulty. In cerebrospinal meningitis the majority of the cocci are situated within the polymorphonuclear cells. Dissolved antigenic material, probably of polysaccharide type, may frequently be demonstrated in the spinal fluid. A few drops of the supernatant fluid are layered gently on to a similar quantity of monovalent or polyvalent antimeningococcal precipitating serum in a Dreyer's tube. Usually a fine white opaque disc of precipitation becomes apparent in a few minutes. If it does not, the tube is incubated in a water-bath for 1–2 hours at 37° C. Both Rake (1933*b*) and Maegraith (1935) have obtained very satisfactory results with this method (see also Alexander and Rake 1937). In Maegraith's series of 120 cases, a positive reaction occurred on 116, while of 180 control fluids, all but 2 were negative. No other method affords such a rapid diagnosis.

(2) *Immediate plating.* As soon as the spinal fluid is withdrawn, it should be streaked in quantities of 1 ml. over 2 or 3 plates of ascitic agar or Gordon's trypagar (Gordon *et al.* 1916). These plates should be incubated immediately, or if this is impossible, they must be transmitted to the laboratory in a warm container. The

less their temperature falls below 37° C., the more likely is growth to occur, and the shorter is its lag period. Growth is often greatly favoured by the addition of 5–10 per cent. CO_2 to the atmosphere. In favourable circumstances colonies should be formed within 18 hours. These are examined with a hand lens, and films are made in the usual manner. A growth of Gram-negative diplococci having been obtained, it is important to ascertain their serological type. If there is a heavy growth on the plates, this may be suspended in a small quantity of saline, heated to 65° C. for 1 hour, standardized to 500 million per ml., and tested against the type sera; incubation should be performed by the partial immersion method in a water-bath for 4 hours at 50° C. A more rapid result is said to be obtained by the use of specific antisera prepared by the injection of chickens; readings can be made in about 5 minutes (Phair, Smith and Root 1943). If the growth is insufficient for a tube test, or if an immediate answer is required, slide agglutination may be used instead (Bell 1920*b*), but the results should always be checked by the tube method. If there is insufficient growth on the primary plates to allow of either method of agglutination, subcultures must be made on to fresh plates, and the growth examined after 24 hours. The fact must not be forgotten that one variety of organism found in meningitis, *N. flavescens*, may produce a golden-yellow pigment (Branham 1930).

It must be pointed out that not all strains are readily agglutinable by the available type sera. Strains from sporadic cases are usually less readily agglutinated than those isolated during an epidemic. Much depends upon the strains selected for the preparation of the agglutinating sera (see Griffith 1917, Scott 1917, Bell 1920*a*, Murray 1929, Branham 1932, Rake 1933*a*).

It is important to test the fermentation reactions of the organisms isolated. For this purpose colonies should be inoculated into glucose, maltose, and sucrose peptone water, containing 10 per cent. of ascitic fluid or blood serum. The meningococcus produces acid in glucose and maltose, but not in sucrose; *N. flavescens* is without action on any of the sugars. The final identification of any strain must be made on the basis of morphological, cultural, fermentation, and serological reactions.

(3) *Incubation of the spinal fluid with subsequent subcultivation.* It is always wise to incubate 5 ml. of the fluid at 37° C. in a sterile tube, in case direct plating proves negative. Sometimes the organisms develop in the fluid itself, when they fail to do so in cultures made at the time of lumbar puncture. As soon as turbidity appears, the fluid should be subcultured on to suitable media, and the resulting colonies identified in the usual way.

The frequency with which positive cultures are to be expected depends partly on the stage of the disease and partly on the carefulness of one's technique. Flack (see Report 1917), in an examination of 55 specimens of cerebrospinal fluid, obtained the following results:

	No.	Culture Positive. Per cent.
In clear fluids	15	33
In slightly turbid fluids . .	13	61
In turbid fluids	27	96

In the early stages of the disease before the spinal fluid is purulent, the proportion of positive cultures is much lower than in the later stages. In chronic

cases the fluid, after being frankly purulent, may clear again, and the organisms become increasingly difficult to isolate. Ultimately they disappear and can no longer be demonstrated.

Cultivation from the Nasopharynx.—At the time of lumbar puncture a nasopharyngeal swab should be taken. There are two advantages in this practice. First, a positive culture may be obtained from the nasopharynx, especially in the early stages of the disease, when the spinal culture is negative. Second, the nasopharyngeal swab may yield a heavier growth than the spinal plate, and so enable the serological typing of the organisms to be carried out more rapidly. Since the nasopharyngeal and spinal strains are almost invariably of the same type, there is little danger of error in this procedure.

For examining the nasopharynx, West's swab may be used; this consists of a wire curved at one end, fitted with a pledget of cotton-wool, and enclosed in a glass tube. As soon as the swab has been taken it should be streaked over a plate of ascitic agar or Gordon's trypagar; if the latter medium is used, it is advisable to smear 2 or 3 drops of fresh blood over the surface. The plates must be incubated immediately, or kept in a warm container. The following day they are examined for the typical lenticular colonies of meningococci. The further examination of these colonies should be performed in the same way as that of the spinal colonies. If the swab cannot be inoculated at once on to a suitable medium, it should be stored in a tube with a little blood agar at the bottom with the swab touching the agar (Downie 1940). Whatever type of swab is used, it is important to avoid its becoming contaminated with saliva, otherwise the meningococci may be overgrown by salivary streptococci.

The serological typing of meningococci isolated from the nasopharynx often presents difficulties, particularly during inter-epidemic periods (see Chapter 23). During the course of an epidemic, the proportion of agglutinable to inagglutinable strains may rise considerably, depending probably upon the selection of a virulent epidemic strain of well-defined antigenic specificity (Report 1920). The higher the carrier rate is, the more likely are the organisms to be agglutinated.

Examination of the Blood.—(1) *Cultivation.*—An attempt may be made to cultivate the meningococcus from the blood, although this procedure is not adopted as a routine. For this purpose 10 ml. of blood should be withdrawn from the median basilic vein, and distributed in 1 ml. quantities over a series of 10 ascitic agar plates; or two flasks containing 150 ml. of 33 per cent. ascitic fluid broth may each be seeded with 5 ml. blood. Positive results may be expected in 25 per cent. of cases examined during the first week of the disease.

(2) *Demonstration of Antibodies.*—The blood may be examined for specific antibodies in special cases; but the diagnostic value of such tests is very doubtful, and they must never be regarded as a substitute for the direct cultural examination.

It has been found that agglutinins are frequently present in the blood serum of patients suffering from cerebrospinal fever (Dieudonné 1906, MacGregor 1910). Von Lingelsheim (1908) examined the sera of 593 patients. On the 1st day of disease 24·1 per cent. gave a positive agglutination reaction; from the 6th to the 20th day, 52·7 per cent.; after the 21st day, only 26·7 per cent. of positive reactions were obtained. The titre varies considerably. Bettencourt and França (1904) found that it was usually 1–10 to 1–50; occasionally titres of 1–200 or even 1–1000 were met with. Von Lingelsheim (1905*a*) gives the following figures:

146	agglutinated at	1-10
86	„ „	1-25
30	„ „	1-50
8	„ „	1-100
1	„ „	1-200
149	failed to agglutinate at	1-10

Gates (1918) found agglutinins almost constantly in the blood of carriers of 4 to 16 weeks' standing; the titre was generally 1-16 to 1-32.

It is seen that agglutinins are not present in more than 50 per cent. of cases as a rule. MacGregor (1910) found that when marked toxæmia was present, there were generally no agglutinins; likewise in chronic and in abortive cases. They were present in greatest quantities in cases with an acute onset and fairly high fever. Other observers (Elser and Huntoon 1909) have found the agglutination reaction to be too irregular for diagnosis.

Houston and Rankin (1907), studying the opsonic content of the serum of patients suffering from cerebrospinal fever, found that it was raised in 25 per cent. of patients on the 2nd day of the disease, in 60 per cent. on the 5th day, and in 96·1 per cent. after the 6th day. They stated that the opsonin test was of great value in the diagnosis of suspected cases. MacGregor (1910) found opsonins present in greatest quantity during the 2nd and 3rd weeks of the disease; like agglutinins, they are said to be most abundant in cases with acute onset. Cruickshank (1941) states that circulating antibodies can often be demonstrated in the second week of the disease, and perhaps even earlier in cases of meningococcal septicæmia.

Examination of Petechial Skin Lesions.

The presence of meningococci in petechial spots was demonstrated by Muir (1919), using the cultural method. In a considerable proportion of cases the organisms can be found microscopically in smears. McLean and Caffey (1931) were successful by this means in 14 out of 18 cases in children, and Tompkins (1943) in the Army in 39 out of 48 cases. The petechial spot—macules are unsatisfactory—should be punctured with a Hagedorn needle, while the surrounding skin is pinched so as to prevent the access of capillary blood to the lesion. Small drops of blood should be smeared on to a slide and stained with Giemsa. Typical intracellular diplococci with the adjacent surfaces flattened can be detected in this way, and confirmed by a Gram stain. They can often be found when blood culture is negative.

Post-mortem Examination.—In the examination of bodies at autopsy, it is important to take cultures within 12 hours of death if possible; the meningococcus dies out rapidly, and though it may be found microscopically in smears from the meninges, cultures often prove to be sterile. For cultural purposes, it is best to use the pus on the meninges; if there is no pus visible in this situation, the interior of the lateral ventricles should be carefully examined; occasionally some may be found in the posterior horn. In cases of doubt the spinal cord should be removed, and a careful search made, especially of the posterior aspect.

Prophylaxis.

We have seen that the meningococcus lives as a parasite in the nasopharynx. Under normal conditions it will be found in a certain proportion of apparently healthy persons. Mathews and Herrold (1918) found it in 4·4 per cent. of non-contacts in a military camp during an epidemic; Ponder (1918) in 13 per cent. of non-contact civilians in a non-epidemic period; Scott (1916) in 22 per cent. of non-contact hospital out-patients; Nabarro (1917) in 6·3 per cent. of children attending a hospital. As a conservative estimate we may say that in non-epidemic

times the meningococcus is present in 2–8 per cent. of healthy civilians; the actual proportion will depend to a certain extent on the time of year.

We have also seen that the meningococcus is transmitted from carriers to normal persons around them. The carrier is clearly of great importance in the continued propagation of infective material. It is of interest, therefore, to ascertain how long the organism survives in the nasopharynx. Gordon and Flack (see Report 1917) and Mathews and Herrold (1918) observed that there are two classes of carriers; in the one class, only a few colonies of meningococci are found on the plates streaked from a nasopharyngeal swab; in the other class, there is an almost pure growth of meningococci. The former class clears up rapidly; the latter may carry the organism for months.

Flack (see Report 1917) gives the following table relative to the length of time that carriers may remain infective (Table 122).

TABLE 122

	Contact Carriers.	Per cent.	Non-contact Carriers.	Per cent.
Under 2 weeks	20	16·1	12	19·7
From 2–4 „	45	36·3	32	52·5
„ 4–6 „	26	21·0	5	8·2
„ 6–8 „	14	11·3	2	3·3
„ 8–10 „	4	3·2	7	11·5
„ 10–12 „	5	4·0	—	—
Over 12 „	10	8·1	3	4·9

Thus the percentage of carriers of more than 4 weeks' duration was 47·6 per cent. in the case of 124 true contacts, and 27·9 per cent. in the case of 61 non-contact carriers. A comparison of the persistence of different serological types of the meningococcus in the nasopharynx failed to reveal any marked variation between them. Norton and Baisley (1931) in the civilian epidemic at Detroit found that 72·4 per cent. of contact carriers became negative within a fortnight. Not all carriers, however, clear up. During inter-epidemic times some persons carry the meningococcus for months and even years; the organism, in fact, takes its place in the normal nasopharyngeal flora. Convalescent cases of cerebrospinal fever, it may be noted, harbour the meningococcus in their nasopharynx for a long time; Embleton and Steven (1919) found the average length of carriage to be about 6 months.

Apart from droplet infection by carriers, it is possible that indirect infection may play a small part in the spread of the disease. Dopter (1921) considers that this may occur occasionally by handkerchiefs, bedding, clothes, and drinking vessels contaminated with nasal mucus. It is difficult to say how frequent such indirect infection may be, but in view of the extreme susceptibility of the meningococcus to drying and to cold, we may regard it as negligible. Neither in barracks nor in civilian households is this method of infection to be compared with the direct infection by nasal mucus sprayed from the carrier.

In connection with the prevention of cerebrospinal fever much has been written on the advisability of detecting and isolating carriers. Hachtel and Hayward (1911) were able to eliminate the disease from an orphan children's home by isolating the carriers, treating them with topical applications of anti-

whether in civilian life the manifest advantages of the method are outweighed or not by its disadvantages.

Prophylactic Vaccination.—The value of prophylactic vaccination is difficult to ascertain. No definite conclusions can be drawn from the earlier attempts (see Sophian and Black 1912, Greenwood 1916, Gates 1918). More recently Zrůnek and Feierabend (1931) endeavoured to immunize the Czechoslovak army. Soldiers whose names began with A-M were vaccinated, while those with names beginning with N-Z were left as controls. Three doses—2,000, 4,000, and 4,000 million—of a vaccine prepared from recently isolated local strains killed at 60° C. for 1 hour were given. The inoculations were made in December, just prior to the usual seasonal outbreak of the disease. Of 21,280 subjects vaccinated in 1926 and 1927, 5 developed meningitis and 3 died. Of 19,684 controls, 6 developed meningitis and 3 died. Unfortunately for the success of the experiment, meningitis was much less prevalent in 1927 and 1928 than in previous years. The evidence, so far as it goes, does not, however, suggest that vaccination confers a high degree of immunity to the disease. Riding and Corkill (1932) carried out a large series of vaccinations on natives in the Northern Sudan. One group of 10,691 men received a polyvalent meningococcal vaccine, another group of 10,451 received T.A.B. vaccine, while 245,058 served as controls. No significant protection was afforded by either of the vaccines.

Serum Treatment.—The results of this treatment recorded by different observers are somewhat confusing, and their significance is by no means easy to assess.

Jochmann (1906) was the first to introduce this method of treatment. He prepared a polyvalent serum by injecting horses, first with dead then with living cultures, and found that it would protect mice against 4-6 M.L.D., provided it was given 24 hours beforehand in a dose of 0·5 ml. subcutaneously or intraperitoneally. He showed that the serum contained agglutinins, bactericidins and bacteriotropins. He then employed his serum for the treatment of human patients; he gave it in 20 ml. doses subcutaneously or intrathecally; 12 out of the 17 cases treated recovered.

Kraus and Doerr (1908) prepared a serum by the injection of goats and horses with broth filtrates and endotoxin; the resulting product was able to neutralize the endotoxin *in vitro*, and to protect guinea-pigs against subsequent injection with a lethal dose of toxin.

In spite of the work done by the early observers, it is to Flexner (1907*c*, 1912, 1913, Flexner and Jobling 1908*a*, *b*) more than to any other, that we owe our present knowledge of the value of serum treatment. In 1907 he (1907*c*) prepared sera from the goat, horse, rabbit and guinea-pig. He found that in monkeys the simultaneous injection of serum and of meningococci intraspinally was not followed by the development of severe symptoms, although the organisms persisted for a time in the spinal fluid; further, by injecting serum 6 hours after the infecting dose, the monkey—already seriously ill—could be saved from apparently impending death. Encouraged by these results he proceeded to try the serum on human cases. Together with Jobling (Flexner and Jobling 1908*a*) he prepared his serum by subcutaneous injection into horses at weekly intervals of living cocci and autolysate alternately; an attempt to standardize it was made by titrating it according to the complement-fixation test, and against the autolysate in guinea-pigs, but neither method was found to be quantitatively reliable. The serum was distributed from the Rockefeller Institute in New York to all parts of the world; reports were

received from the practitioners using it, and in 1913 these were finally collected and analysed (Flexner 1913).

Excluding fulminant cases dying within 24 hours of serum injection, cases with mixed infection of the meninges, cases of intercurrent infections, and hopelessly chronic cases, of a total of 1,294 patients treated by their serum, 894 recovered and 400 died, giving a mortality of 30·9 per cent. This mortality must be compared with that of untreated cases, *from which, however, similar exclusions had not been made*. At this time the mortality of cerebrospinal fever in Great Britain was from 70–80 per cent., in Germany 42–67 per cent., in France 75 per cent., in Belgium 77·7 per cent., and in Italy 55·6 per cent., in Palestine over 80 per cent., in Greece 58·6 per cent., and in the Transvaal 74 per cent. From these figures it may be concluded that the mortality of non-serum-treated cases was about 70 per cent. In 1,211 treated cases the reports were sufficiently full to permit an analysis of the effect of the time of administration (Table 123).

TABLE 123

Time of Injection.	No. of Cases.	Recovered.	Died.	Per cent. Recovered.	Per cent. Died.
1–3 days	199	163	36	81·9	18·1
4th–7th day . . .	346	252	94	72·8	27·2
Later than 7th day .	666	423	243	63·5	36·5
Totals	1,211	838	373	69·2	30·8

This table brings out the beneficial effect of treatment of cases admitted early to hospital. The mortality of cases in which serum treatment was commenced before the 4th day was only half that of cases not treated till the 2nd week or later.

Another interesting point is the fatality of serum-treated patients at different ages (Table 124).

TABLE 124

MORTALITY ACCORDING TO AGE IN SERUM-TREATED PATIENTS.

Age.	No. of Cases.	Recovered.	Died.	Per cent. Recovered.	Per cent. Died.
Under 1 year . .	129	65	64	50·4	49·6
1–2 years .	87	60	27	69·0	31·0
2–5 „ .	194	139	55	71·6	28·4
5–10 „ .	218	185	33	84·9	15·1
10–20 „ .	360	254	106	70·6	29·4
Over 20 „ .	288	180	108	62·5	37·5
Age not given . .	18	11	7	61·1	38·9
Totals	1,294	894	400	69·1	30·9

From this table it is seen that infants under 1 year of age have the highest mortality, and children between 5 and 10 years the lowest. The high infantile mortality may be largely due to the difficulty of diagnosis, so that serum treatment is often not commenced till after the disease has lasted a week, and partly also to the technical difficulties inherent in lumbar puncture and in serum administration in the very young.

A further study of the records seemed to show that in cases favourably influenced by serum, recovery occurred fairly rapidly; not infrequently the temperature, which in untreated patients generally falls by lysis, fell by crisis. This was especially noticeable in cases treated early.

Following the injection of serum, the blood leucocytes fell from a figure of 20,000–40,000 to normal within a week or so; the spinal fluid became progressively clearer, the pus cells grew fewer, and the meningococci disappeared. On the other hand, in cases not influenced by serum the leucocytosis remained high; the spinal fluid showed an increase in the turbidity, and in the number of pus cells and living meningococci.

In cases untreated by serum which did not prove rapidly fatal, the disease often passed into a chronic stage lasting for months; or if recovery occurred, it was apt to be followed by a relapse. In serum-treated cases, however, it was found that the patients either died or recovered completely. Only very rarely did the disease become chronic. Relapses were likewise uncommon; they occurred in only 8 per cent. of cases, and frequently yielded to further serum treatment.

Another favourable indication of the value of serum was the diminution in the proportion of patients who developed complications. These complications—irido-choroiditis, panophthalmitis, deafness due to internal ear disease, pleurisy, pericarditis, endocarditis, arthropathies, insanity and others—are not uncommon in patients who recover naturally. In serum-treated patients such complications were few; the only one which occurred with any frequency was deafness; this was doubtless due to the early spread of the disease to the internal ear; the sooner serum treatment was begun, the less likely was this spread to occur.

Summing up Flexner's results, it would appear that by serum treatment the mortality was considerably reduced, the frequency of relapses diminished, the incidence of chronic cases abolished, and the proportion and the severity of the complications lowered very considerably.

There are numerous records by other workers of cases treated by serum with results essentially similar to those obtained by Flexner (see Netter and Debré 1911, Adshead 1918, Rolleston 1918, Hines (Report 1920), Dopter 1921, Wadsworth 1931, Sturdee and Scott 1933, Banks 1938). Univalent sera have, on the whole, been more effective than multivalent sera.

Before judging the value of serum treatment there are certain factors of importance to be considered.

The first concerns the **mode of preparation** of the serum. This has varied in different countries.

Flexner and Jobling (1908*a*) used subcutaneous injection of living diplococci and of an autolysate alternately; this method, though effective, requires considerable time—10 months or more—before the serum is sufficiently potent for use. Amoss and Wollstein (1916) described a more rapid procedure, yielding a multivalent serum of high titre in 8 to 12 weeks; the essential feature of their method consists in giving 3 successive intravenous injections of living meningococci at daily intervals, followed by a rest of 8 days, before the administration of a fresh series. Numerous strains of different types are included. A. S. Griffith (see Report 1920) followed this method in his preparation of sera for the Medical Research Council, with the exception that he used strains of only one type for each horse; the resulting sera were therefore univalent. It is important in selecting the cultures to be used for immunization to choose strains which are representative of those present during an epidemic. F. Griffith (1917) advises the use of the highly complex strains which are found more commonly at the height of an epidemic than at any other

period. In the preparation of a multivalent serum Wadsworth and Kirkbride (1926) favour the use of 4–6 carefully selected strains rather than of larger numbers. On the ground that meningococci produce a soluble toxin (see Ferry, Norton, and Steele 1931), Ferry (1932, 1934) recommends antitoxic sera prepared by injecting horses with the type-specific toxins. The evidence, in his opinion, suggests that antitoxic are of more importance therapeutically than antibacterial sera. Maegraith (1938), however, was unable to confirm this. The antibody in native sera may be concentrated by suitable fractionation (Neal *et al.* 1928, Murdick and Cohen 1933, 1935), but whether such sera are more efficacious in practice than ordinary sera still remains to be seen.

The next factor to be considered is the **titration** of the serum. As yet there is no laboratory method by which the therapeutic power may be correctly gauged.

Flexner and Jobling (1908*a*) relied partly on the complement-fixation test, and also on titration against autolysate in guinea-pigs. Nicolle, Debains and Jouan (1918) used the complement-fixation test alone; Jobling (1909) the opsonin content; Amoss and Wollstein (1916) the agglutinin content; Hitchens and Robinson (1916) a mouse-protection test; Gordon (see Report 1920) the anti-endotoxic value; and de la Rivière and Roux (1925) a precipitin test. As the results given by these different methods vary considerably, it is clear that they cannot all be satisfactory. Experience during more recent years has similarly failed to reveal any substantial agreement between different workers on the best method of titration. Wadsworth (1931) favours agglutination, Zozaya (1932) and Mishulow (1935) precipitation, Ferry, Norton and Steele (1931) and Konowa and Nikolsky (1934) toxin-neutralization, Sickles (1933) a neutralization test based on skin reactivity, and Zdrowdowsky and Voronine (1932), Branham (1935), and Rake (1935*b*) some form of protection test. On the whole, opinion is now crystallizing in favour of the intraperitoneal mouse protection test (Mishulow *et al.* 1936, Rake 1937*a*, Branham *et al.* 1938, Branham and Pittman 1940). There seems to be little relation between the agglutinin and the protective titres in any given serum, but according to Rake the protective antibody content is fairly well correlated with the amount of immune nitrogen precipitable by type-specific polysaccharide (see also Pittman *et al.* 1938). Standardization in terms of some significant unit is clearly desirable before liberation of a serum from the laboratory; otherwise normal sera, or sera containing only a minimal antibody content, may be distributed by certain agencies. What this unit is to be still awaits international agreement. (For general discussion, see Murray 1929.)

Another factor is the **dose** of serum to be injected.

In an acute case in an adult it is advisable to inject 20–30 ml. of serum to start with, after having drawn off rather more than an equivalent amount of cerebrospinal fluid. The quantity of fluid which should be withdrawn varies from case to case; if it is under great pressure, it may be allowed to run until it is coming at the rate of 1 drop per second. Sometimes 120 ml. may flow away before this rate is reached. But the patient must be watched very carefully during the process, and if any untoward signs are observed, the flow must be stopped immediately. Generally it is better, if the fluid is under great pressure, to withdraw about 50 ml., and to repeat the lumbar puncture 12 hours later. The serum should be injected at least once a day for the first 4 or 5 days; sometimes it is desirable to give it twice daily. As in diphtheria, the amount given must be judged by the clinical condition of the patient. In fulminant cases, for example, greater risks may be taken than in less acute cases.

The **route** of injection is also of importance. Since meningococci are frequently present in the blood stream it has been advised that the serum should be given not only intrathecally but also intravenously. Herrick (1918) treated 137 cases by spinal injections with a mortality of 34·3 per cent.; and 128 cases by combined spinal and intravenous injections with a mortality of only 14·8 per cent. Further, he found that the greater

the amount of serum injected, the lower was the mortality. He advises giving about 100 ml. intrathecally and 400–600 ml. intravenously. Fewer complications were encountered when the combined method was employed. In the pure meningococcal septicæmias without coincident meningitis, the serum should always be administered intravenously. In chronic cases, with blockage of the spinal canal, serum should be injected sub-occipitally into the cisterna magna (see Report 1931). Very favourable results are said to follow this method (Cassoute *et al.* 1933, Alliezand and Carbonel 1933, Sepet *et al.* 1933, Robertson 1935). In cases that develop arthropathies, serum may be advantageously injected into the inflamed joints.

These are the main factors influencing serum treatment—the mode of preparation, the method of titration, the amount injected, and the route of injection. Taking all these into consideration, the results obtained must be considered as relatively favourable. It would seem that in cases adequately treated with a good univalent serum, Type I in particular, the mortality may be reduced by over 50 per cent. The adjustments that have been made in arriving at certain of these figures are, however, clearly unjustifiable, and so far as we know serum has never been tested under statistically satisfactory conditions. To do this, it would be necessary to give the serum to alternate cases in an epidemic, and to treat both series of cases in other respects in identically the same way. This would mean performing a lumbar puncture on the control cases with the same frequency as on the serum-treated cases, and replacing the fluid withdrawn by normal serum. The effect of lumbar puncture alone is probably of value. Until such a series is tried, we shall not be able to form a just opinion of the specific activity of the serum itself. The facts, however, that the earlier the serum is administered, the better are the results; that certain batches of sera appear to be more efficacious than others; and that the combined intrathecal and intravenous method gives a lower mortality than the intrathecal method alone, seem to us to point in favour of the therapeutic value of the serum itself.

Chemotherapy.—The introduction of the sulphonamide group of drugs has greatly influenced the case fatality of the disease. On this, all observers are agreed. Numerous figures might be quoted to indicate the reduction in mortality that has followed the use of these drugs, but so many factors—choice of drug, dosage, route, age of patient, and stage, nature and severity of disease—affect the result that comparisons, unless given in considerable detail, are apt to be misleading. As an example, however, it may be stated that Harries (1942) treated 500 consecutive cases of all ages in the Cardiff city isolation hospital with a gross mortality rate of 8·6 per cent.; this figure included every case admitted, even those that died within a few minutes of reaching hospital. Sulphapyridine was used for 471 of the cases, sulphathiazole for the remaining 29. In his series, as in those recorded by other observers (see Beeson and Westerman 1943, Report 1944), the case mortality was lowest in young adults and highest in infants and old people. Experience with different drugs has varied. Sulphapyridine has been widely used, but there is evidence that sulphanilamide may be better (Report 1944). Sulphathiazole has been recommended by Banks (1941) and others, and in the United States sulphadiazine has been favoured. It is important to institute therapy at the earliest possible moment, but experience suggests that the large doses recommended by Banks (1939) are not always necessary.

Whether the combined administration of sulphonamides and serum offers any advantage over sulphonamide treatment alone is still undecided. Both Amies

(1940) and Branham (1940*b*) have reported favourably on combined treatment in experimental infections of mice, but clinical reports (see Banks 1939, Beeson and Westerman 1943, Report 1944) do not seem to bear this out. On the other hand it must be remembered that exact comparisons on patients are difficult to make, and that unless all cases are treated by the same observer using the alternate method of administration, the results are apt to be misleading. There is certainly no convincing evidence that the serum does harm, and there is reason to believe that it may be of benefit in infections with drug-resistant strains. If it is given along with sulphonamide, it should be injected intravenously rather than intrathecally. More recently, penicillin has been suggested for the treatment of cerebrospinal meningitis, but it is too early to assess its value in this respect. According to Rosenberg and Sylvester (1944), intravenous or intramuscular injection of a suitable dose results in the appearance of penicillin in adequate concentration in the cerebrospinal fluid, suggesting that intrathecal administration is unnecessary.

Pneumococcal Meningitis

This form of meningitis occurs as a complication of lobar or broncho-pneumonia, and is commoner in children than in adults. Not infrequently in children it is secondary to middle-ear disease. Sometimes a primary pneumococcal meningitis is seen. The pneumococci are present in large numbers in the cerebrospinal fluid, which is turbid and full of pus cells; the cocci may be recognized by their appearance as Gram-positive, lanceolate, capsulated, and mostly extra-cellular diplococci. Cultures are best taken on to blood agar or ascitic agar. The type of coccus may be determined in the usual way. In untreated cases the disease is almost uniformly fatal. Serum treatment with univalent type serum may be tried, preferably by the combined intravenous and intrathecal routes, but far more favourable results are to be expected from the administration of the sulphonamides (see Coleman 1940).

Streptococcal Meningitis

Streptococcal meningitis is most frequently due to extension from middle-ear disease, especially in children, and to perforated wounds of the skull. The cerebrospinal fluid is turbid, and contains large numbers of pus cells and of streptococci, which are usually of the β-hæmolytic type. Before the sulphonamide era recovery was regarded as exceptional, though Watson-Williams (1938) points out that early mastoidectomy, combined with repeated lumbar puncture and the administration of antistreptococcal serum, may result in a substantial proportion of recoveries. In practice, sulphonamide therapy should be instituted as early as possible, along with appropriate surgical measures.

Tuberculous Meningitis

Tuberculous meningitis is probably always secondary to a tuberculous focus in some other part of the body, but, as it is often difficult to determine the site of the primary lesion, even at autopsy, the disease not infrequently appears to be primary. Osler (Osler and McCrae 1920) states that it may occur during the 1st year of life, but is commonest between the 2nd and 5th years; it is, however, not uncommon in adults, particularly as a terminal infection in pulmonary tuberculosis. The laboratory diagnosis is often difficult. Lumbar puncture reveals a fluid which may be limpid, and may contain only mononuclear cells. The protein

content is, however, always raised, while both the sugar and the chloride content are much diminished. The number of cells is generally increased, the most usual count being between 50 and 400 per c.mm. In most cases these cells consist chiefly of lymphocytes, but these are almost always associated with numerous polymorphonuclear and often with some plasma cells. If the fluid is allowed to stand at room temperature, a clot not infrequently forms; this should be spread on a slide, and stained by Ziehl-Neelsen. If no clot forms, the fluid should be centrifuged at high speed for half an hour, the deposit spread on albuminized slides, or fixed with methyl alcohol, and stained with Ziehl-Neelsen. It is often only after prolonged search that a group of tubercle bacilli is found. As well as being examined microscopically, the clot or centrifuged deposit should be injected intramuscularly into a guinea-pig, which is killed after 4–8 weeks (see Chapter 59). Sometimes it is possible to culture the organisms when none are visible microscopically; for this purpose the deposit should be distributed over 3 or 4 Dorset egg tubes, and incubated for a month. The bovine type is responsible for about 23 per cent. of cases in this country.

The disease is uniformly fatal. A few cases have been reported which have recovered, but it is possible that they are explicable by an error in diagnosis.

Influenzal Meningitis

This form is met with sporadically; it is not commoner during an influenza epidemic. Most cases appear to be primary. It was first described by Slawyk (1899), and has since been recognized by a number of workers (see particularly Cohen 1909, Ritchie 1910, Henry 1912, Rivers 1922, Schnyder 1925, Koch and Krämer 1931, Eddy 1933, Neal *et al.* 1934, Dahr 1934). Neal and her colleagues met with 111 cases of this type among a total of 2,727 cases of meningitis. The incidence is highest in childhood. It is rare under 2 months or over 6 years of age (Fothergill and Wright 1933). About 60–80 per cent. of cases occur during the first 2 years of life. The disease closely simulates cerebrospinal meningitis. It usually lasts 10–20 days, and has a case mortality rate of about 95 per cent. The cerebrospinal fluid is under pressure, is cloudy or purulent, has a high cell count, especially of polymorphs, and shows a variable increase in protein and often a marked decrease in sugar. Gram-negative bacilli are present with the typical Pfeiffer morphology, but sometimes accompanied by long thread forms. In the early stage of the disease they are intracellular, but later they become free in the fluid. On suitable media they can be cultivated from the spinal fluid, and often from the blood, and from the purulent joint exudates that occur not infrequently as a complication of this disease. In their nutritional requirements and their indole production they resemble *H. influenzæ*, but they differ from this organism in being capsulated, in producing distinctive colonies on Levinthal's medium, in forming a type-specific polysaccharide, and in being considerably more virulent for laboratory animals; they correspond to Pittman's Type b (see Pittman 1931, Mulder 1939). Occasional strains, however, of the respiratory type are encountered (Gordon, Woodcock and Zinnemann 1944). Inoculated intraperitoneally into rabbits, guinea-pigs, rats, and mice, they often give rise to a fatal septicæmia and to purulent effusions in the serous cavities. Treatment with sulphonamides is often successful (see Davies 1943, Archer and Singer 1943). Alexander and Leidy (1943), on the basis of mouse experiments, recommend sulphadiazine given alone or in combination with antiserum (see also Boisvert *et al.* 1944).

Other Forms of Meningitis

Occasionally meningitis may be caused by organisms, such as *B. aerogenes*, *Bact. coli*, Friedländer's bacillus (Gordon and Norton 1930), *Salm. typhi*, *Salm. enteritidis* (Stevenson and Wills 1933), *Salm. paratyphi B* (Patterson 1942), *Pf. mallei*, *Br. suis* (Hartley *et al.* 1934, Hansmann and Schencken 1932), the gonococcus (Strumia and Kohlhas 1933, Branham *et al.* 1938), *Diplococcus mucosus* (Cowan 1938, Bray and Cruickshank 1943), *Actinomyces bovis* (Henry 1919), and *Leptospira icterohæmorrhagiæ* (Marie and Gabriel 1935, Mollaret and Erber 1937).

For meningitis due to filtrable viruses, see Rivers and Scott (1935) and pp. 1932–1935.

CHAPTER 65

GONORRHŒA

HISTORY.—That gonorrhœa has a history stretching back into antiquity we know, but we are entirely ignorant of the time and place of its first appearance. There is little to suggest that the disease has altered in its nature during the passage of time; it appears to run its course now in the same way as it has done for hundreds of years. It therefore differs from many diseases in which the clinical picture alters with the centuries. The explanation of this may lie in the absence of both natural and acquired immunity in man.

The causal agent, the gonococcus, was discovered by Neisser in 1879, who found it in 35 cases of gonorrhœa which had lasted for varying lengths of time, from 3 days to 13 weeks. He failed to find it in non-gonorrhœal pus, such as that accompanying chancres, buboes, etc., or in simple vaginal discharges; he demonstrated its presence in 7 cases of ophthalmia neonatorum, and in 2 cases of adult ophthalmia. Though unable through illness to complete his investigation, he placed the ætiological rôle of the gonococcus on a footing which has never since been seriously challenged. It was left, however, to Bumm (1885*a*, *b*) to cultivate the organism, and by inoculation experiments on human subjects to demonstrate its pathogenicity in pure cultures.

Gonorrhœa in Adults.

Gonorrhœa is an acute infectious disease, generally characterized by primary invasion of the genito-urinary tract, and frequently complicated by secondary disturbances of greater or less severity.

By far the commonest method of infection is by sexual intercourse. In man the anterior urethra is first attacked. After an incubation period of 2 to 3 days, a mucoid discharge appears, which rapidly becomes purulent. At first the gonococci are mostly extra-cellular, but soon they are taken up by the pus cells, which ingest them in large numbers; as many as 100 may be counted in a single cell.

In cases not successfully treated at this stage, the gonococci pass backwards to the posterior urethra, where they infect the glands; from this situation they are extremely difficult to dislodge. The prostate, too, is frequently infected; indeed it is generally a prostatitis which is responsible for the chronicity of the disease.

In women the disease starts with an acute urethritis; later the cervix uteri becomes infected, and may remain so for a number of years.

Complications of Gonorrhœa in Adults.—Though infection may remain localized to a small area of the genito-urinary tract, it is quite common for it to spread either by direct continuity or by the blood stream to other parts of the body, and set up complications. This may occur during either the acute or the chronic stage of the disease. Thus the gonococcus has been found in epididymitis (Colombini

1898, Witte 1900), in proctitis (Bumm 1884), in salpingitis, in arthritis (Bordoni-Uffreduzzi 1894, Neisser 1894), in tenosynovitis (Hocheisen 1906), in vesiculitis (Wynn 1905), in cystitis, in ophthalmia (Neisser 1879), less frequently in peri-renal abscesses (Colombini 1898), in pyelonephritis, and in peritonitis.

In rare instances the disease may be very acute, the organisms gaining access to the blood stream and giving rise to a bacteræmia, which may be followed by pyæmia. In these cases, which may prove fatal, there is wide-spread infection throughout the body, and post mortem there may be found endocarditis, myocarditis, less frequently pericarditis, subcutaneous and intra-muscular abscesses in different situations, polyarthritis, phlebitis, pleurisy, general adenitis, pneumonia, and septic infarcts in the spleen and kidneys. Several such cases have been reported (Leyden 1893, Ghon and Schlagenhaufer 1898, Thayer and Lazear 1899, Strong 1904, Duval and Lewis 1905, Wynn 1905, Hocheisen 1906, Jenkins 1922). Gonococci have been demonstrated in nearly all these lesions, and have often been obtained in pure culture from the blood stream both during life and after death (Thayer and Lazear 1899, Duval and Lewis 1905, Wynn 1905, Jenkins 1922). Meningitis is a rare complication (see Strumia and Kohlhas 1933). A few cases are on record of a gonococcal stomatitis (Crosby 1905), or parotitis (Colombini 1898); from the latter situation the organisms have actually been cultivated.

Gonorrhœa in Children.—Children suffer from ophthalmia neonatorum and from vulvo-vaginitis. The former is due to infection at birth with gonococci present in the maternal passages, the latter to infection of towels in infants' hospitals: but not all cases of ophthalmia neonatorum and vulvo-vaginitis are of gonorrhœal origin, and not all Gram-negative cocci found in these diseases are gonococci.

At one time ophthalmia neonatorum was responsible for a large proportion of cases of blindness, but since the introduction of the Credé preventive treatment it has become much less common.

Vulvo-vaginitis is mainly an institutional disease. Like puerperal fever and the old hospital gangrene, it is very much more frequent in institutions where large numbers of patients are collected together. Thus Fischer (1895), reporting in 1895 on the incidence during the past 2 years of the disease in the children's hospital at Altona, said that of 50 cases all but 10 were contracted in the hospital; of these 10, some had apparently been imported from other hospitals. Holt (1905) reported on no fewer than 273 cases of the disease in the Babies' Hospital, New York, during the preceding 11 years. The disease is spread from one cot to another by the use of towels and other linen that are imperfectly sterilized. Once introduced into a hospital or institution, it is a most difficult disease to eradicate; only scrupulous care in technique, constantly maintained for months on end, will prove successful eventually. The disease has a way of cropping up after it has lain dormant for weeks; to relax precautions too soon is but to court disaster. By no means all cases of vulvo-vaginitis in children are of gonococcal origin. Other organisms, such as hæmolytic streptococci and staphylococci, are often responsible, and possibly Pettit's bacillus (Hardy 1941, Osmond 1944). A diagnosis of gonorrhœal infection should therefore never be made unless the gonococcus is demonstrated. For a review of the disease, see Benson and Steer (1937).

It will be seen that the parts of the body attacked are not the same in adults as in children. Gonorrhœal ophthalmia is common in infants, rare in adults; gonorrhœal vaginitis is common in infants and children up to 5 or 6 years old, but is uncommon in adults. A similar difference is noted in the complications; thus

in adults the internal genito-urinary organs are frequently attacked ; in children these are rarely attacked, but on the other hand acute peritonitis is fairly common in female children, but rare in adults. Thus we may say that the vagina and conjunctiva are specially susceptible during infancy, and the internal genital organs during adult life. The mucosa of the urethra and rectum are susceptible throughout life. Both in adult gonorrhœa in the female, and in vulvo-vaginitis of children, the rectum is stated to be frequently involved—in 20–30 per cent. of the cases.

Reproduction of the Disease in Man.—Direct experiments on man to ascertain the pathogenicity of the gonococcus have been almost entirely confined to urethal injection. By this route, using pure cultures of the organism, it is comparatively easy to set up a typical attack of gonorrhœa, both in males and in females (Bumm 1885*a*, Wertheim 1891, Bordoni-Uffreduzzi 1894, Finger *et al.* 1895, Colombini 1898). The injection of a young culture into the urethra is followed in two or three days by a purulent urethritis, which pursues a course similar to that occurring in the natural disease, often lasting for months in spite of treatment. Gonococci are present in the pus cells, and may be recovered in pure culture.

Not only is it possible to convey the disease to a normal person by injection of pure cultures, but it is possible to incite an acute attack in a patient who is suffering from chronic gonorrhœa. There is apparently little, if any, immunity acquired to the disease. Injection into the human urethra of killed gonococci gives rise to a transitory purulent inflammation (Scholtz 1900).

Steinschneider and Schäffer (1895) injected large numbers of living gonococci into the subcutaneous tissues of healthy persons, and found that no reaction of any sort occurred.

Using gonotoxin, de Christmas (1897) found that the injection of 1 ml. into the human urethra gave rise to a urethritis, coming on in 2 hours, and subsiding after about 2 days. No immunity was established ; the same effect was reproduced after each of 5 successive injections. Wassermann (1898) injected 0·1 ml. of toxin subcutaneously into himself ; 4 hours later a reaction set in, characterized by local inflammation, slight shivering, an evening rise of temperature, headache, and pains in the limbs and joints. He then injected the same dose subcutaneously into two patients suffering from chronic gonorrhœa ; similar results followed, accompanied by swelling of the local glands. No immunity to the toxin was established ; the same reaction was repeated after 5 separate injections at 4-day intervals.

FIG. 282.—*Neisseria gonorrhœæ* in film of pus from acute gonorrhœa (× 1000).

Diagnosis.

The diagnosis of gonorrhœa depends in the main on the demonstration of the causative organism. The characteristic morphology and staining reaction of the gonococcus, and the fact that a considerable proportion of the cocci are always intracellular, make it possible to confirm the clinical diagnosis by microscopical examination of the purulent discharge in *acute* infections (Fig. 282). Wherever any element of doubt exists, cultures should be prepared on

a suitable medium (see Chapter 23). In *chronic* cases it may be extremely difficult to demonstrate the gonococcus in films, or to isolate it in culture. This holds particularly true for the female, where a diagnosis on microscopic grounds alone can rarely be made. Appropriate measures must be taken to obtain material for examination from the situation most likely to be the seat of chronic infection—the deep urethral glands and the prostate in the male, the Bartholinian glands and the cervical glands in the female. It may be noted that the fluid withdrawn from the joints in gonorrhœal arthritis is frequently sterile, and that the same is true of pus withdrawn from the Fallopian tube in chronic cases of gonorrhœal salpingitis.

For diagnostic cultivation the method described by McLeod and his colleagues (1934) is to be strongly recommended. The medium used is a 10 per cent. heated blood agar prepared from broth made according to Wright's (1929, 1933) method, *i.e.*, extraction of the minced meat for 45 minutes at 60° C. in the presence of 1 per cent. peptone and 0·2 per cent. Na_2HPO_4, followed by steaming. The broth should have a reaction of pH 7·4, and the minimum amount of agar necessary to give stability to the medium should be added. The plates are first incubated for 18 hours at 36° C. in a closed jar containing air, 8 per cent. of which has been replaced by CO_2, and then for 24 hours under ordinary aerobic conditions. A 1 per cent. solution of tetramethyl-*p*-phenylenediamine hydrochloride is then poured over the plate and run off immediately. The effect of this solution is to turn gonococcal colonies a bright purple colour. Medium-sized convex translucent colonies that rapidly turn bright purple and are found microscopically to consist of Gram-negative diplococci may be provisionally accepted as gonococci. For further identification, when necessary, the colonies are picked off, and studied culturally and biochemically. A rapid provisional method for establishing their identity based on the solubility of gonococci in N/10 NaOH is described by Cantor, Shelanski and Willard (1942). Occasionally colonies giving the oxidase reaction and consisting of Gram-negative diplococci are isolated from the genito-urinary tract which subsequent examination shows are not true gonococci. Organisms of this type are unlikely to give rise to more than 1·5 per cent. of erroneous diagnoses. Cultural methods are greatly superior to direct microscopical examination of smears (see, for example, Gibbons 1937, Carpenter, Leahy and Wilson 1938, Sewell, Clarke and Nelson 1941); nevertheless a certain number of cases do occur in which the smear method is positive when the cultural method is negative. The greatest caution, however, must be taken in chronic cases in identifying the gonococcus on morphological appearances alone. As Beck (1933) points out, confusion is often caused by staphylococci and streptococci, which may occur in pairs and fail to retain the Gram stain. If swabs for cultural purposes cannot be inoculated at once on to a suitable medium, measures must be taken to prevent death of the gonococci. Cox and McDermott (1943) recommend collection of the exudate on to a small wooden toothpick; this is dropped into a tube, 50 × 6 mm., containing 0·6 ml. of a mixture made up of equal parts of sterile distilled water and defibrinated horse blood to which 1/30,000 crystal violet and 5 mgm. per 100 ml. of *para*-aminobenzoic acid are added. The tube is closed with a corked paraffined stopper. By this means successful results may be obtained, even after transmission through the post.

In chronic or latent gonorrhœa, or in cases of rheumatism, iritis, etc., in which a latent gonococcal infection is suspected, failure to demonstrate the presence of the gonococcus can never be regarded as definite evidence that this organism is absent from the tissues. In such cases certain indirect methods of diagnosis are available.

The Complement-Fixation Test.—Müller and Oppenheim (1906) were the first to apply this test to clinical practice, obtaining a positive result in a case of gonorrhœal arthritis. Since then it has been used by a large number of workers (Watabiki 1910,

Schwartz and McNeill 1911, 1912, Keyes 1912, Kolmer and Brown 1914, Irons and Nicoll 1915, Dixon and Priestley 1919, Priestley 1919, Magner 1920, Smith and Wilson 1920, Herrold 1921, Torrey and Buckell 1922, Torrey *et al.* 1922, Walker 1922, Rubenstein and Gauran 1923, Osmond and Oliver 1929, Kristjansen 1931, Price 1933, Thjøtta and Waaler 1933, Schröpl 1934).

The technique of the reaction requires extreme care, and for a detailed description of the various methods employed the student is referred to the Medical Research Council's Report (1918)—a report which has been largely drawn on in the present section on diagnosis. It is generally recognized that a polyvalent antigen and an anti-sheep hæmolytic system are most satisfactory.

Great care is necessary in the interpretation of the reaction. The following points must be borne in mind: (1) the reaction does not become positive for at least 2 weeks after infection; (2) it is often negative in simple cases of anterior urethritis in the male, and of urethritis in the female; (3) it is generally positive in cases in which complications are present; (4) it remains positive for about 3 months after clinical cure; (5) a single negative reaction is of little importance; (6) two or three successive negative reactions during the course of 4 to 6 weeks are of considerable importance in excluding the presence of the disease; (7) a positive reaction becoming negative about 3 months after clinical cure is strong evidence in favour of real cure; (8) a positive reaction denotes the recent activity in the body of a focus of living gonococci.

Sera of patients who have never had gonorrhœa are said to be consistently negative. The injection of vaccines interferes with the test, as the gonococcal antigen itself is able to stimulate the production of specific immune bodies; the reaction is therefore valueless in vaccine-treated patients. Only in one other disease may the reaction be positive—namely in cerebrospinal meningitis; the two diseases are so easily differentiated on clinical grounds that confusion is unlikely.

Table 125 shows the percentage of positive reactions which may be expected in certain gonococcal infections. It has been compiled largely from the results of Schwartz and McNeill (1911, 1912), Kolmer and Brown (1914), Smith and Wilson (1920), Walker (1922), Torrey, Wilson and Buckell (1922), and Rubenstein and Gauran (1923).

It is seen that complications in the male genital system and in the joints give the highest percentage of positive results. The test is therefore of considerable value in those cases in which microscopic and cultural tests are most likely to fail. It is of especial value in chronic pelvic disease.

The complement-fixation test is being regarded with increasing favour. The more recent reports record a very small proportion of false positive reactions—usually under 1 per cent.—and a higher proportion of positive results than is given in Table 125. Price (1933) in particular, using a modified technique, claims to have obtained a very high proportion of positive results, ranging from 27 per cent. in the 1st week after exposure to 100 per cent. in the 5th week.

The figures given by Tulloch (1929) from Dundee may also be quoted.

Complement fixation	positive:	microscopical findings	positive:	433
„	„	negative:	„	„	negative: 737
„	„	positive:	„	„	negative: 163
„	„	negative:	„	„	positive: 215

The figures given in the last row refer mainly to early cases in which the complement-fixation reaction had not had time to become positive. Those in the

TABLE 125

Acute Gonorrhœa, 2–4 weeks	48%	positive	reactions
Subacute and Chronic Gonorrhœa	61%	„	„
Epididymitis	82%	„	„
Prostatitis	80%	„	„
Vesiculitis	88%	„	„
Metritis	68%	„	„
Salpingitis	77%	„	„
Vulvo-vaginitis	50%	„	„
Arthritis	82%	„	„

third row refer mainly to chronic cases, and it is in such cases that the complement-fixation test finds its main value.

Precipitin Reaction.—This method was advocated by Robinson and Meader (1920) who found that discharges from gonorrhœal inflammations gave a precipitin reaction with antigonococcus serum, even when no gonococci were to be found microscopically. Kelley (1922), who tried this reaction, was unable to confirm their results. The test cannot yet be relied on for diagnosis.

More recently Meinicke (1931) has introduced his *Klarungsreaktion* (MKR test) and Müller (1932) his *Ballungs-Reaktion* (Im.B.R. test) for the diagnosis of gonorrhœa. According to Schröpl (1934), who made comparative observations on these tests, both of them give a higher proportion of non-specific reactions than the complement-fixation test, especially with syphilitic sera. One or other of them may be used, however, in conjunction with the complement-fixation reaction in order to amplify and control the results obtained by this test.

Skin Reaction.—Bruck (1909) found that patients with gonorrhœa showed a marked skin reaction to dead gonococci. Kohler employed this test in diagnosis, and found it to be valuable in many cases.

Irons (1912) prepared a glycerinated suspension from several strains of gonococci, which he called gonococcin. Inoculation was made on the skin with the point of a needle. After a few hours, in positive cases, a papule appears, surrounded by hyperæmia, reaching its maximum size in 24 hours, and disappearing after several days. The diameter of the papule and the hyperæmic zone around it is 5 mm. or more. The reaction was found to be generally positive at some time during the course of the disease, but in cases of severe infection, it might remain consistently negative. On the whole, it does not appear to be sufficiently regular to be of value in diagnostic work.

Prevention and Treatment.

Prevention is intimately associated with early diagnosis and efficient treatment. The mode of infection indicates sufficiently clearly the ways in which the disease can be avoided, and the reservoirs of infection which exist in any community. The problem is one of personal and social hygiene.

Opinions as to the value of vaccine treatment differ considerably. The evidence available does not lend itself to statistical analysis (see Aronstam 1908, Ballenger 1908, Butler and Long 1908, Churchill and Soper 1908, Hamilton and Cooke 1908, Bruck 1912, Lees 1919, Thomson 1919).

Antibacterial sera have been employed in the treatment of gonorrhœa, but without any conspicuous success. The infection is not of a type in which we should expect such sera to be of value (see Rogers 1906, Torrey 1906, Jötten 1921).

Of recent years the whole problem of treatment has been altered by the introduction of the sulphonamide group of drugs and penicillin. Of the sulphonamides, sulphathiazole and sulphadiazine have so far given the best results. In males,

4 days' treatment with 5 gm. of sulphathiazole a day is said to cure over 90 per cent. of acute cases (Harrison 1942; see also Osmond 1943). Early acute cases in females likewise respond well to treatment, but chronic cases present far greater difficulty (Osmond 1944). In spite, however, of the outstanding success of the sulphonamides, numerous failures are experienced. The cause of these is not perfectly understood. In some instances the infecting strain is resistant to sulphonamide or becomes resistant as the result of insufficient dosage; in others the natural defence mechanism appears to be inadequate; and in others there is a suggestion that the patient's serum possesses properties antagonistic to sulphonamide action (see Editorial 1944). Fortunately most cases that prove resistant to sulphonamide treatment respond well to penicillin. Acute cases may be cured by the intramuscular injection of about 20,000 units every 3 hours till five doses have been given. Gonococci disappear within a few hours of the beginning of treatment, and within 24 hours the urethral discharge dries up completely. How far penicillin treatment will prove successful in chronic cases, and whether penicillin-resistant strains will increase as this form of treatment becomes more prevalent, it is as yet impossible to say. It may be noted that treatment with penicillin is now the method of choice in gonorrhœal ophthalmia

One further method is available, namely that of induced pyrotherapy. This depends on the fact that in culture the gonococcus is almost completely destroyed by exposure for 2 hours to a temperature of 41·5°–42° C. (see Carpenter *et al.* 1933). The patient's temperature is raised by placing him in a special cabinet heated with carbon filament lamps, or by passing high-frequency currents through his trunk. The aim is to keep his temperature at a sufficiently high level for a sufficient length of time to bring about *in vivo* sterilization of the gonococci. This is a very severe form of treatment, not without its hazards (Wallace and Bushby 1944), but it holds out hope for the patient when other methods have failed (Warren *et al.* 1937).

CHAPTER 66

SCARLET FEVER, AND OTHER DISEASES DUE TO HÆMOLYTIC STREPTOCOCCI

SCARLET FEVER

Our present conception of the mechanism of infection and resistance in scarlet fever affords an excellent example of the solution of a bacteriological problem by the convergence of evidence obtained along many different lines of investigation.

The fact that long-chained streptococci are frequently present in the throat during the early stages of scarlatinal infection has been known since the early days of bacteriology. Baginsky and Sommerfeld, in 1900, recorded their presence in each of 700 cases. As soon as the differentiation of streptococci into hæmolytic and non-hæmolytic types had been established, it became clear that the species so constantly associated with scarlet fever was *Str. pyogenes*. The streptococcal infection appears not to be strictly confined to the tonsils or fauces; Hektoen, in 1903, reported the isolation of streptococci from the blood in 12 per cent. of the cases which he studied, and noted that this evidence of bacteræmia was not necessarily of bad prognostic significance. In spite of such observations as these, there was great hesitation in accepting the undoubted association between hæmolytic streptococci and scarlet fever as one of cause and effect; and this hesitation was natural. *Str. pyogenes* was already known as the essential cause of various acute suppurative and septicæmic infections in man; and there seemed no means of differentiating between the strains isolated from scarlet fever, and those isolated from such conditions as cellulitis or erysipelas. A septic form of scarlet fever was well recognized by clinicians, in which hæmolytic streptococci were by general consent accorded the principal causative rôle, and it was commonly agreed that these organisms were the most frequent causative agents in such complications as otitis media; but the general trend of opinion was to regard *Str. pyogenes* as an important secondary invader, playing a part similar to that of *Str. pneumoniæ*, or of *Str. pyogenes* itself, in the secondary pneumonia of measles, influenza, or whooping cough. Moreover, the bacteriological findings had, in some directions, an appearance of inconsistency. Jochmann (1905), for instance, reported his failure to isolate streptococci from the blood, or tissues, of patients dying within a few days from a malignant form of the disease.

The suspicion remained, that the association might be closer than that implied by the dominant view; and, whenever a new method of bacterial differentiation was applied to the *Streptococcus* group, an attempt was made to compare scarlatinal strains with those derived from other sources. The use of fermentation tests failed to distinguish any group which was constantly associated with scarlet fever; though some observers recorded a high frequency of particular fermentative types

in association with this disease. The introduction of serological methods of differentiation seemed to offer a better hope of solving this problem, and Moser and von Pirquet (1902), Meyer (1902) and Rossiwall and Schick (1905) reported that scarlatinal strains of hæmolytic streptococci could be differentiated by agglutination tests. These findings were, however, not confirmed by other observers (Neufeld 1903, Aronson 1903, Hasenknopf and Salge 1903); and the problem remained unsolved. In the light of our present knowledge we can hazard the guess that, along these lines alone, it would have remained insoluble. It is true that the renewed interest in the antigenic analysis of the hæmolytic streptococci which followed on the studies of Dochez, Avery and Lancefield (1919) led to the collection of important new data, and that the results recorded by Bliss (1920, 1922), Gordon (1921), Eagles (1924), and Stevens and Dochez (1926*a* and *b*) went far to confirm and extend the earlier observations of Moser and von Pirquet; but the more detailed studies, which were undertaken in the years before the war by Griffith (1926, 1927, 1928, 1934, 1935), Smith (1926, 1927*a*), James (1926), Gunn and Griffith (1928), McLachlan and Mackie (1928) and others (see Chapter 24), revealed a high degree of antigenic heterogeneity among the hæmolytic streptococci, and made it abundantly clear that there was no one antigenic type to which the name *Str. scarlatinæ* or *Str. pyogenes* var. *scarlatinæ* could be applied, though some types were far more commonly associated with scarlatinal infections than others, just as some types of pneumococci are isolated more frequently than others from cases of lobar pneumonia. Practically all strains of hæmolytic streptococci that have been isolated from cases of scarlet fever have been found to belong to Lancefield's Group A (*Streptococcus pyogenes*), the strains falling within this group being characteristically pathogenic for man (see Lancefield 1928, and, for further details of antigenic structure, Chapter 24). Of a total of 8,096 strains reviewed by Schwentker, Janney and Gordon (1943*b*), 7,995 belonged to Group A, 2 to Group B, 39 to Group C, 21 to Group G, and 39 to unidentified groups. Thus, about 99 per cent. of all strains fell into Group A. The isolation of occasional strains of Group C or G need occasion no surprise, since these organisms are not infrequent in the normal throat.

In Britain, Types 1, 2, 3 and 4 were most frequently isolated from cases of scarlet fever by Griffith (1934) (see also Cooke and Neisser 1937, Green 1937, Neisser 1939, de Waal 1940, 1941). In Gelsenkirchen, Germany, Gundel and Wustenberg (1937) found Types 4, 3, 5, 1 and 2. In Tokyo, Kodama and his colleagues (1937, 1939) record predominance of Types 1–4 in the winter of 1936–37, of Types 2, 4, 8 and 10 in 1937–38, and of Types 2, 4 and 8 in 1938–39. The common types in Australia are different. In Sydney, White, Rudd and Ward (1939) found that Types 17, 1, 4, 6, 5, and a local type "Wade" predominated in 1936, and Types 11, 4, 17, "Wade" and 1 in 1938. Keogh and his colleagues (1939*a*) could find no Types 1, 2 or 3 in Adelaide, where Type "Wade" predominated; in Melbourne, however, Type 2 predominated in 1939–40, the remainder of the cases being associated with Types 17, "Wade," 11 and 6 (Kelsey 1941, Keogh, Simmons and Wilson 1941). The American figures are again different. Bailey (1939), for example, in Chicago found Types 2, 3 and 6. In a general survey of scarlet fever streptococci in the U.S.A., Keefer and his colleagues (1942) found that Types 15, 13, 11, 1 and 2 predominated in 1938–39; and among soldiers in a U.S. Army camp, the scarlet fever types were 3, 17, 19 and 1 (Hamburger *et al.* 1944). Bynoe (1943) records that in Ottawa, 1940–42, the prevalent types were 3, 19 (17), 4, 2, 6 and 14.

Most observers are agreed that the scarlet fever types in a given community also predominate in other varieties of streptococcal infection—tonsillitis, pharyngitis, puerperal

fever and so forth—but occasionally there are marked differences. Thus Hamburger and his colleagues (1944) noted that Type 6 was, among others, prevalent in throat infections in a camp, but never gave rise to scarlet fever. As regards the severity of the scarlet fever produced by different types, no generalization is possible, though in some communities, certain types—for example, Type 1 in Britain, and Type " Wade " in Australia —have been found to be associated with the severer infections.

Once it had been shown that *Str. pyogenes* was constantly associated with scarlet fever it was natural to inquire whether this organism would reproduce the disease in any experimental animal. The results obtained when the usual laboratory animals were inoculated with cultures of hæmolytic streptococci, from any source, showed that the guinea-pig, rabbit and mouse differed in their resistance to this bacterial species, and that the type of infection produced varied in relation to the virulence of the particular strain inoculated, and the route of inoculation; but there was no indication of any correlation between a particular type of experimental infection and the source from which the infecting strain was obtained; nor did any of the inoculated animals develop lesions which bore any obvious relation to scarlet fever in man.

Dochez and Sherman (1922), however, found that the subcutaneous inoculation of guinea-pigs with streptococci embedded in agar gave rise to a fever accompanied by an erythematous rash, which later desquamated. Landsteiner, Levaditi and Prasek (1911) produced scarlet fever in monkeys by inoculation of the throat with faucial exudate from scarlatinal patients. *Str. pyogenes* was recovered from the fauces of animals so infected, but these strains failed to reproduce the disease in other monkeys.

The proof that scarlet fever is caused by infection with hæmolytic streptococci rests on a series of observations that have been made on man himself, and these observations have elucidated the pathogenesis of the disease, as well as its causation.

In 1914 Krumwiede, Nicoll and Pratt recorded an instance in which a laboratory worker was accidentally infected by sucking into her mouth a suspension of living streptococci. After an incubation period of three days she passed through a typical attack of scarlet fever. In 1921 Dick and Dick attempted to reproduce scarlet fever in a series of human volunteers by inoculating the throat with various organisms isolated from scarlatinal patients, including hæmolytic streptococci; none of these volunteers developed the typical disease, though some developed tonsillitis. In 1923 the same observers carried out another series of experiments, using a strain of *Str. pyogenes* which had been isolated from the finger of a nurse who was suffering from surgical scarlatina. Of five volunteers, who were inoculated by swabbing the fauces with a broth culture of this organism, three showed no reaction, one developed a sore throat with fever, but without rash, and one passed through a typical attack of scarlet fever. Five other volunteers, who were swabbed with filtrates from these cultures, showed no reaction. When these were later swabbed with living cultures, one of them developed scarlet fever. Toyoda and others (1931) record the production of scarlet fever in three volunteers by swabbing the throat with hæmolytic streptococci from scarlatinal patients.

It has thus been shown that certain strains of *Str. pyogenes* are capable of causing typical scarlet fever in susceptible human beings; but these susceptible individuals are in a minority among any random sample of the adult population.

The explanation of this unequal distribution of resistance has emerged from a series of studies carried out along somewhat different lines. In 1918 Schultz

and Charlton recorded a phenomenon which has played an important part in the subsequent study of the disease. They found that 1 ml. of normal human serum, injected into the skin of a patient displaying a characteristic scarlatinal rash, produced a blanching of the rash in the immediate neighbourhood of the injection. This property was shared by the serum from a patient who was convalescent from scarlet fever, but not by serum withdrawn from a patient during the height of an attack. It has since been shown that the Schultz-Charlton phenomenon is given by about 60 per cent. of normal sera (Dochez 1925). This reaction was originally regarded as the result of the presence, in normal serum, of some substance which was removed from it during an attack of scarlet fever; but Mair (1923) recorded an instance in which he was able to demonstrate that the serum of a child gave a negative Schultz-Charlton reaction before an attack of scarlet fever, and a positive reaction after convalescence. He noted that sera obtained from young children, who have not had scarlet fever, give a much higher proportion of negative reactions than sera from a random sample of adults; and he put forward the view that the positive reaction is the result of the development of a specific antitoxin, which neutralizes the toxin present in the skin of a scarlet fever patient. According to this view the rash, and probably other features of the scarlatinal syndrome, are to be regarded as toxæmic in origin.

It had long been known that certain strains of hæmolytic streptococci yielded filtrates which, in large doses, were toxic for laboratory animals: but the susceptibility of these animals was so slight that little or no progress was made in the study of such toxic filtrates before the investigation by Dick and Dick (1924*a*, *b*, 1925*a*, *b*) of their action in man. Their results showed that Berkefeld filtrates of broth cultures of scarlatinal strains of *Str. pyogenes* contained a toxic substance which produced a typical erythematous reaction, when injected intradermally, in a proportion of normal persons who had not suffered from scarlet fever (see p. 591). This local reaction was induced by the injection of 0·1 ml. of a 1 : 1,000 dilution of the particular toxic filtrate employed. This test, which is more fully described on p. 1467, has since been applied to large samples of the normal population; and the distribution of positive and negative reactors, which is closely analogous to that revealed by the application of the Schick test in the case of diphtheria, is in full accord with the view that the great majority of young children are susceptible to the erythrogenic toxin, but, with advancing years, acquire an active antitoxic immunity, either by passing through an attack of the clinical disease, or, more commonly, by an immunizing infection with a toxin-producing streptococcus without the production of the characteristic scarlatinal syndrome (see Chapter 49 and Zingher 1924).

The administration of larger doses of erythrogenic toxin to susceptible persons has yielded even more demonstrative results. In a number of cases such doses have induced a generalized reaction with fever, nausea, vomiting and a transient scarlatiniform rash. Most of the recorded instances of this "miniature scarlet fever" were observed during the earlier stages of the study of the erythrogenic toxin; but it still occurs occasionally, when a particularly susceptible person is undergoing immunization with doses of the ordinary size (see p. 1473). This reaction recalls the observation of Gabritschewsky (1907), who, during the inoculation of a large series of persons with a killed culture of scarlatinal streptococci, noted a scarlatiniform reaction in a number of his subjects. It did not occur in persons who had had scarlet fever, nor in persons injected with anti-scarlatinal

serum prepared (Moser 1902) by inoculation of horses with scarlatinal streptococci (see also Szirmai 1942).

Additional evidence has been contributed by the studies of Trask and Blake (1924), who record the following significant observations. A toxic substance can be demonstrated in the serum of patients acutely ill with scarlet fever, which produces a typical skin reaction when injected intracutaneously into persons who have not had scarlet fever, and whose serum gives a negative Schultz-Charlton reaction (*i.e.* contains no antitoxin). Such injections produce no reaction in persons whose serum gives a positive Schultz-Charlton reaction. This toxic substance is not neutralized by a human serum which gives a negative blanching test, but is readily neutralized by a human serum which gives a positive blanching test. It is not neutralized by normal horse serum, but it is readily neutralized by a horse anti-scarlatinal serum.

We may also note here that during the course of scarlet fever there is usually evidence of a serum response to other products of *Str. pyogenes*. Recovery is associated with an increase in the resistance of the plasma to streptococcal fibrinolysin (Tillett and Garner 1933, Tillett, Edwards and Garner 1934, Stuart-Harris 1935, Bau and Kleu 1936, Waaler 1936, Gordon and Balteanu 1937) and with an increase in antibody to the O streptolysin of *Str. pyogenes* (Todd 1932, Longcope 1936, Green 1941, Mote and Jones 1941, Rantz, Kirby and Jacobs 1943). Rantz and his colleagues also noted that in 13 of 24 patients with scarlet fever there was a significant rise in agglutinins for the infecting type of streptococcus.

Taking this evidence as a whole, there seems little doubt as to its import. Scarlet fever in man is a disease caused by infection with *Str. pyogenes*. The causative organisms are, for the most part, localized in the throat, though there may be a transient bacteræmia in some cases. The clinical manifestations of the disease result from the action of a soluble toxin, which is absorbed from the local lesion and carried to the susceptible cells and tissues. The varying susceptibility of children and adults, and of the same age groups in different social environments, depends upon the presence or absence of circulating antitoxin. Animals other than man, and perhaps certain anthropoid apes, do not reproduce the disease, even when experimentally infected, because of their much greater resistance to the scarlatinal toxin.

Only one other point requires consideration at this stage, the unity or diversity of the toxins produced by different strains of *Str. pyogenes*. In much of the earlier work there was an overt or implicit suggestion that the scarlatinal toxin was a characteristic and distinctive product of those races of hæmolytic streptococci which were associated with scarlet fever. Subsequent studies have shown that this is not the case. Omitting any detailed descriptions of the results recorded by individual investigators (Park and Spiegel 1925, Lash 1926, Kirkbride and Wheeler 1926, Eagles 1926, Smith 1927*b*, McLachlan 1927, Okell and Parish 1928), the evidence at present available tends to support the following conclusions. The production of a soluble exotoxin, giving typical skin reactions in man, is characteristic of *Str. pyogenes* in general, and not of scarlatinal strains in particular. There is, however, some evidence that toxigenicity is a more constant character in scarlatinal than in non-scarlatinal strains. Qualitative differences in the toxins formed by different strains of Group A streptococci have been described by Wadsworth and Coffey (1935), who studied toxins made from 314 strains. Of these, 77·4 per cent. were neutralized by one monovalent antistreptococcal goat serum, 10·5 per cent. by a second, and 10·5 per cent. by a third serum. The remaining 1·6 per cent. of toxins were neutralized by a combination of the sera. Fraser (1937) reported similar results. It would appear that ordinary commercial antitoxin should neutralize a high proportion of all toxic strains. Whether an erythrogenic toxin is produced by any other species, or group, of hæmolytic streptococci is as yet uncertain (see Chapter 24).

The Bacteriological Diagnosis of Scarlet Fever.

Scarlet fever, in its characteristic clinical form, is a disease in which a throat infection with *Str. pyogenes* is associated with a rash produced by the erythrogenic toxin, and a syndrome that is, in the main, toxæmic in origin. A diagnosis of a throat infection caused by *Str. pyogenes* is not therefore a diagnosis of scarlet fever; indeed, a clinician will frequently be concerned in distinguishing a throat infection of this type from a case that, because of other criteria, would fall into the scarlet fever category. A throat swab has not, under these conditions, any great diagnostic value. We should expect to isolate *Str. pyogenes* from every case of scarlet fever; but we should also expect to isolate it from many cases to which that diagnosis would not be applicable. It may be noted that the attempt to isolate *Str. pyogenes* from genuine cases of scarlet fever is by no means uniformly successful. In our own experience about 10 per cent. of throat swabs taken during the first three or four days of the disease have failed to yield this organism, though we have almost invariably isolated it during the second half of the first week. As a routine it is advisable to inoculate two blood agar plates and one gentian violet blood agar plate, and to incubate one of the blood agar plates anaerobically in order to favour hæmolysis. Very occasionally, *Str. pyogenes* fails to form hæmolytic colonies, and its recognition becomes particularly difficult (Coburn and Pauli 1941, Colebrook *et al.* 1942).

The Diagnosis of Susceptibility or Immunity to Scarlet Fever.

For this purpose we use the Dick test, in which a small dose of toxin is injected into the skin of one arm, and a dose of inactivated toxin into the skin of the other, to serve as a control. The amount of toxin injected is 0·2 ml., containing one skin-test dose, and the method of performing the test is essentially the same as in the Schick reaction (see p. 1376). The following differences should, however, be noted.

The erythrogenic toxin is far more heat resistant than diphtheria toxin. The filtrate that is to serve as a control must therefore be heated at 96° C. for 45 minutes. A control test should never be omitted (see Burton and Weir 1944).

The skin reaction to the erythrogenic toxin occurs more rapidly than the reaction to diphtheria toxin. A bright red flush appears within 6 to 12 hours, attains its maximum in about 24 hours, and then fades rapidly, so that it may be almost invisible on the third day. The pseudo-reaction, when it occurs, is smaller and less intense than the true positive reaction and fades more slowly. In this last respect, the time relations of the positive and pseudo-reactions in the Dick test are the reverse of those in the Schick test, and the times of reading the Dick test must be adjusted accordingly.

The interpretation of the test does not differ from that of the Schick reaction. A positive reaction (positive on the test arm and negative on the control) or a combined reaction (positive and pseudo on the test arm and pseudo on the control) indicates susceptibility. A negative reaction (negative on both arms), or a pseudo-reaction (pseudo on both arms), indicates immunity.

We can safely assume that, except in young infants (see p. 1078), a negative reaction indicates the presence of antitoxin in the circulation or the tissues; this has been shown to be the case in many instances, and the Schultz-Charlton reaction affords further proof of the presence of antitoxin in the serum of resistant persons. Because of the difficulty of titrating scarlatinal antitoxin, to which we shall refer in a later section, we have, however, much less information in regard

to the level of antitoxin that confers an effective immunity than we have in the case of diphtheria.

Although the reactions to the Schick and Dick tests have the same general significance, experience has shown that they are not equally reliable. It is, for instance, uncommon for any Schick-negative person to develop diphtheria, while almost every case of diphtheria is found to be Schick-positive at the onset of the disease. In the case of the Dick test the figures, though tending quite clearly in the same direction, are of a different order.

Thus Toyoda and his colleagues (1929) note that 41 of 305 cases of scarlet fever (14 per cent.) were known to be Dick-negative shortly before infection, They give the proportion of cases that are Dick-negative during the early stages of the disease as 23–59 per cent., according to different observers, and the proportion negative during convalescence as 82·3–91·7 per cent. Okell (1932) records similar observations—22 Dick-positive reactors among 119 cases of scarlet fever 3 to 12 weeks after the onset of the disease—and notes that a considerable proportion of persons who have had scarlet fever in early life and are almost certainly immune give positive reactions. Freudenberg (1941) Dick-tested 303 children 6 weeks after the onset of an attack of scarlet fever, and found that only 38 per cent. of 236 children aged 0–10 years were Dick-negative, whereas 63 per cent. of 67 children aged 10–16 years were negative. The association of immunity with a negative Dick-reaction was clearly shown in the incidence of a second attack in 1200 children, of which the Dick-tested children were a sample. Of the 19 second attacks observed, 18 occurred in the 0–10 year age group, and one only in the older children.

It would seem a just conclusion, from the evidence at present available, that a Dick-negative reactor is much less likely to contract scarlet fever than a Dick-positive reactor, but that the odds against his doing so are not nearly so high as the odds against a Schick-negative reactor developing diphtheria, and that similarly a Schick-positive reaction is a more reliable indication of susceptibility to diphtheria than is a Dick-positive reaction to scarlet fever. These conclusions should perhaps be amplified by pointing out that, so far as susceptibility to streptococcal throat infection is concerned, there seems to be no difference between Dick-positive and Dick-negative reactors (Schwentker *et al.* 1943*a*, *b*, Kidd 1944). Both types of reactor appear to be equally liable to become symptomless carriers; and the incidence of complications appears to be the same in patients with and without a rash (Hobson 1936, Stebbins *et al.* 1937). The only difference is that a positive reactor is more likely to develop a rash than a negative reactor. Even so, it is a common experience to observe the absence of a rash in Dick-positive persons infected with a strain known to produce erythrogenic toxin.

The Standardization of Erythrogenic Toxin.—One of the great difficulties of the Dick reaction is that involved in the standardization of the erythrogenic toxin (see Okell 1932, Friedman *et al.* 1935). The skin test dose is defined as the smallest amount of toxin that will, on the average, produce an erythematous reaction, 1 cm. in diameter, in the skin of a susceptible person within 24 hours. This dose, in fact, often corresponds approximately to 0·2 ml. of a 1 : 1,000 dilution of a toxic broth culture. Its accurate measurement is, however, almost impossible; in part, because the assumption that any sample of human beings are fully, or equally, susceptible, even when all react positively to a particular dilution of toxin, is quite unjustified; in part, because an adequate supply of susceptible persons on whom the tests can be performed is not easy to obtain. When several fully susceptible persons are available for the titrations, an erythrogenic toxin can

be measured with an approximation to accuracy—a filtrate of strength x can, for instance, be differentiated from a filtrate of strength $2x$— but it is not always easy to do even as well as this (see, for instance, James, Joe and Swyer 1929, O'Brien 1930, Kolchin 1940). This question will be discussed in more detail when we are considering the standardization of antitoxin.

The Epidemiology of Scarlet Fever.

There is every reason to suppose that the epidemiology of scarlet fever is closely analogous to that of diphtheria. In both cases we have diseases characterized by primary throat lesions and a characteristic clinical syndrome that is determined, in the main, by the effects produced by the diffusion of a soluble toxin from the primary lesion. In both, carriers of the causative organism greatly outnumber the clinical cases. In both, the population at large is undergoing, from early childhood onwards, an active immunization resulting from latent or atypical infections (see, for instance, Okell and Parish 1928, Stocks 1930, Allison and Gunn 1932, Okell 1932). They differ, however, in one important respect. Broadly speaking, diphtheria is the only clinical manifestation of *C. diphtheriæ*, whereas scarlet fever is but one manifestation of a wide variety of lesions caused by *Str. pyogenes*.

The earlier observations on the distribution of the causative organism, including those carried out in the authors' laboratory at Manchester and in London (Report 1930, Straker *et al.* 1939), referred to the incidence of hæmolytic streptococci in general, but more recent information is available on the incidence of *Str. pyogenes* in particular. The frequency with which this organism can be isolated from the throat of normal persons not in contact with epidemic streptococcal infection of the respiratory tract varies widely with age, season, country, occupation and doubtless other factors. Thus the following figures may be quoted as examples: healthy children and adults in Melbourne 4·5 per cent. (Keogh *et al.* 1939*b*); school children in Melbourne 13·3 per cent. (Macdonald *et al.* 1940); students, staff and out-patients in hospital at Patna 10·6 per cent. (Chatterjee and Mitter 1941); parturient women in Shanghai 1·8 per cent., and hospital nurses in Shanghai 4 per cent. (Wu 1941); healthy girls in a residential school in Buckinghamshire 4·2 per cent. (Report 1941); patients suffering from measles on admission to hospital at Bristol 11·7 per cent. (Peters *et al.* 1942); Army recruits in Wyoming 8 per cent. (Schwentker 1943); incoming naval recruits in the United States 4 per cent. (Schwentker *et al.* 1943*a*); Bantu children 19·0 per cent. (Murray 1943); patients and nurses in the Birmingham Accident Hospital 19·2 per cent. (Williams and Harper 1944).

On the whole, the carrier rate in the throat of normal persons usually seems to vary between 4 and 8 per cent. It tends to be highest in the winter and spring, and lowest in the summer and autumn months.

In any community, such as a school, where overt infections like tonsillitis or scarlet fever are occurring, even though the number of such cases is small, the incidence of *Str. pyogenes* in the throat tends to be far higher. Carrier rates of 25 or 50 per cent., or even more, are by no means uncommon. In the nose *Str. pyogenes* is much less frequent than in the throat. The normal incidence is below 1 per cent. When it is present in the nose, it is almost invariably found in the throat as well.

We have described on p. 1387 the way in which diphtheria bacilli disappear from the throat during convalescence, and reference to Table 115 will show that about 50 per cent. of diphtheria convalescents have ceased to carry by the 20th day, and 90 per cent. by the 50th day. It has become quite clear that the disappearance of hæmolytic streptococci from the throat during convalescence from scarlet fever is

much slower (see Nicholls 1927, Gordon 1927, Gunn and Griffith 1928, Allison and Gunn 1932, Brown and Allison 1935, Allison and Brown 1937, de Waal 1940); and it would seem that the carrier rate among convalescents on discharge from hospital is usually of the order of 50 per cent. By itself, however, this statement is misleading, unless it is pointed out that the carrier strain on discharge is often different from that on admission. The observations of Allison and Brown (1937), followed by those of numerous other workers (Cooke and Neisser 1937, de Waal 1940, Peters *et al.* 1942), have shown that a variable proportion of scarlet fever patients treated in general wards become cross-infected with a strain of a different serological type. This happened, for example, in 33 out of 47 of Allison and Brown's cases. Many of the patients became infected with two, three, or even four different types in succession. At the time of discharge, after an average stay in hospital of 33 days, 39 patients were still infected. The primary strain disappeared, on an average, after 18 days; the cross-infecting strain persisted for a time varying from a few days to a few weeks.

The result of such cross-infections varies according to circumstances. The infection may remain latent; it may give rise to a transient secondary fever, accompanied or followed by complications such as coryza, tonsillitis, adenitis, or otitis; or it may be responsible for a completely fresh attack of scarlet fever. Allison and Brown (1937) found that the majority of complications occurring in multiple bed wards after the end of the second week in hospital were due to cross-infection. Our own experience would suggest caution in accepting this finding as necessarily true of all hospitals, or of the same hospital at all times.

Though a high proportion of scarlet fever patients are still *infected* on discharge from hospital, it is difficult to say how many of them are actually *infective*. The return case rate does not as a rule appear to exceed 2 per cent., though slightly higher figures are sometimes quoted. Brown and Allison (1935) found that heavy carriers were more likely to prove infective than light carriers, and that patients discharged during the 5th, 6th and 7th weeks were more infective than those discharged earlier. This observation is interpreted as suggesting that the primary infecting strain loses most of its infectivity by the 4th week, and that the cross-infecting strain is still infective at the time of the patient's discharge.

Epidemiological evidence indicates that the great majority of patients infected with streptococci become relatively harmless to their fellows within 3 or 4 weeks. As Griffith (1934) suggests, this may be due to a process of antigenic degradation accompanied by loss of virulence occurring in the throat of a person who has become immune to the particular type of streptococcus with which he is infected. On the other hand, numerous—mainly unpublished—observations have been made showing that an occasional convalescent carrier may remain infective for weeks or even months, as evidenced by his ability to give rise to an outbreak of sore throat or scarlet fever due to the same type of streptococcus in an institution to which he is admitted (Griffith 1934, Moore 1943, Boissard and Fry 1944, Coburn 1944*a*). No bacteriological test is available to distinguish between infective and non-infective strains of *Str. pyogenes*, but it is usually found that persistently infective carriers have some abnormality of the upper respiratory tract, such as a discharge from the nose or ears or enlarged unhealthy tonsils.

The extent to which infection spreads among a population has been studied in institutions (see Griffith 1934, Report 1938, Straker *et al.* 1939, de Waal 1941) and other communities (Schwentker 1943, Schwentker *et al.* 1943*a*, *b*). The attack

rate is subject to considerable variation, seldom, however, in this country exceeding 10 per cent. and often being very much lower. Though there may be a parallelism between the carrier rate and the attack rate, numerous exceptions occur. From institutional studies we have learned that there may be few cases even in the presence of a high carrier rate, and many cases when the carrier rate is low. Hamburger (1944) has had the same experience. This does not seem to be determined wholly or even mainly by the previous streptococcal experience of the children; and as Griffith's studies show, immunity in any case is more or less type-specific. The evidence is far more in favour of Griffith's conception of the existence of strains possessing varying degrees of infectivity and invasiveness (see Stocks 1941). An "epidemic" strain, endowed with both these qualities in a high degree, is liable, when introduced into a given population, to cause a relatively high morbidity, whereas other strains less liberally endowed in these respects will be responsible for merely a few sporadic or "dropping" cases. Analogy with experience of the meningococcus is very close. An additional factor that may exert a considerable effect on the extent and severity of scarlet fever is the coincidence of other respiratory disease, such as measles or influenza (see Gordon 1939). According to Stebbins, Ingraham and Reed (1937), who made a very careful study of milk-borne streptococcal outbreaks in New York State, children under 15 years of age are more infective than older children or adults. The secondary attack rate among household contacts was nearly twice as high when the infecting case was a patient less than 15 years old—13·7 as opposed to 7·3 per cent. The same workers quote figures of 20·0 and 5·3 per cent. for children under and over 15 years respectively in a non-milk-borne outbreak in the same State. Gordon (1940) states that children under 5 years are responsible for about eleven times as many secondary cases as are patients aged 15 years or older. Coburn and Pauli (1941) likewise found that children were much more infective than adults.

Mode of Spread of Infection.

Spread of scarlatinal infection is believed to be usually due to droplets or droplet nuclei, the source of infection being a case of tonsillitis with or without a rash, or a convalescent or normal carrier. Hæmolytic streptococci have been isolated by some observers from the desquamated scales of scarlet fever patients (see Allison and Gunn 1932); but it is unlikely that this is a frequent source of natural infection. Far more important—at least in hospitals—is aerial spread by infected dust. Numerous workers have now demonstrated the presence of hæmolytic streptococci in the *dust* of wards or dormitories housing patients suffering from scarlet fever, tonsillitis, or other streptococcal infection (White 1936, Cruickshank and Godber 1939, Stalker *et al.* 1942, Walter and Hucker 1942, Edward 1944; see also Chapter 91). These organisms may remain alive and apparently virulent for several weeks, especially if protected from light; and there is reason for believing that cross-infection in hospitals is often due to dust derived from the floor, the bedclothes, or the patient's handkerchief.

Apart from personal contact and dust, an important mode of spread of scarlet fever is by *milk*. Since the classical Hendon outbreak of 1885, there have been numerous epidemics, both in Europe and America, in which the epidemiological evidence incriminating milk has been ovewhelming. Of more recent years, this has been supplemented by bacteriological proof, consisting of the demonstration of the same type of infecting organism in the milk as in the throat of the patients.

Though it was believed at one time that the usual source of infection of the milk was the cough spray or ear discharge (see Henningsen and Ernst 1939) of a worker on the farm or in the dairy, the evidence is now pointing more and more in favour of infection of the udder of the cow itself. Most cases of streptococcal mastitis are due to *Str. agalactiæ*; but in occasional cases an organism indistinguishable from *Str. pyogenes* is responsible. In such instances the milk may contain enormous numbers of streptococci that prove highly infective for man. Milk that is contaminated directly from a human case or carrier is liable to be less infective, because *Str. pyogenes* does not usually multiply to any considerable extent in milk at room temperature (Pullinger and Kemp 1937). Several outbreaks have now been recorded in which infection has been traced to the diseased udder of a cow, and in some a human carrier has been found from whom the cow presumably derived its infection (see Jones and Little 1928*a*, *b*, Camps and Wood 1936, Watson 1937, Bendixen and Minett 1938, Henningsen and Ernst 1938, Douglas *et al.* 1941, Dublin *et al.* 1943). Stebbins, Ingraham and Reed (1937) were able to trace infection in 6 out of 7 streptococcal outbreaks of sore throat to mastitis in one of the animals supplying the milk. In the remaining outbreak the milk had been infected from a human source, having been bottled and capped by a worker suffering from an acute sore throat (see also Dublin *et al.* 1943). It may be noted that in these outbreaks, three of which were classified as scarlet fever and four as septic sore throat, patients who gave a history of a previous attack of scarlet fever suffered as severely as those with no such history. The case mortality rates and the incidence of complications were the same in both groups. The only difference was in the frequency of appearance of a rash, the incidence being less than 30 per cent. in the former, and nearly 65 per cent. in the latter group.

The history of scarlet fever provides an excellent example of an infective disease which has exhibited variations in its behaviour during the past half-century. We have already noted the mildness of the type of infection now prevalent; but this mildness is a relatively recent development. In 1861–5 the death rate from scarlet fever, in England and Wales, was 982 per million living; twenty years later it had dropped to half this value; and in the quinquennium 1921–5 it had fallen to 29 per million. This decrease in mortality has, during recent years, been associated with a shift in the age incidence of the disease. The morbidity in the 5–10 age group has increased at the expense of that in the 0–5 age group; while the maximum mortality now tends to fall on older children and young adults.

Prophylaxis

In a disease like scarlet fever, in which the carriers among the general population largely outnumber the cases, we should not expect isolation in fever hospitals to exert any appreciable effect on the frequency of the disease among the population at large; and we may note that Woods (1928), in a statistical study of the incidence of scarlet fever in various districts in this country over a period of 25 years, could find no evidence that isolation had any effect on the prevalence of the disease.

So far as the patient himself is concerned, it must be remembered that cross-infections in hospitals are very common, and that they may be responsible for complications and for increasing the duration of treatment. Their incidence may be greatly reduced by nursing the patients in cubicle blocks, or in wards reserved for patients infected with the same serological type of organism (Allison and Brown

1937, Cooke and Neisser 1937, Peters *et al.* 1942), though the administrative difficulties of the latter method are often considerable. A further measure that promises success is the treatment of floors and bed clothes with dust-laying oils (see Wright *et al.* 1944, Harwood *et al.* 1944, Report 1944, and Chapter 91). In order to diminish the risk of cross-infections, it is wise, if possible, to isolate the patient at home, or, if admission to a hospital is advisable, to restrict the stay to the minimum period necessary—usually 2 to 3 weeks (see Gordon 1940).

Though sulphonamide treatment of the disease itself, apart from complications, seems to be of little value, it is possible that low prophylactic may prove useful in appropriate circumstances. Watson and his colleagues 1943 record apparent success from the daily administration of 1 gm. of sulphadiazine to contacts during an epidemic of scarlet fever in a large naval station. Our own experience has been less favourable (Mollaret and Wilson 1947).

Outbreaks of scarlet fever in schools and other institutions are often very difficult to deal with. Segregation of heavily infected carriers and the passive immunization of contacts may at times be called for, but our control over this disease cannot be compared as yet with the ease with which we can bring outbreaks of diphtheria to a sudden close. Particular care should be taken before admitting convalescents to an institution. Though the majority of convalescent carriers appear to become non-infective within 3 or 4 weeks, occasional carriers may remain infective for much longer and be responsible for introducing the disease into the community. Search should be made in all convalescents for abnormality of the upper respiratory passages, and any child who is found to be a carrier of *Str. pyogenes* and to have rhinorrhœa, otorrhœa, or enlarged unhealthy tonsils, should be regarded as potentially dangerous and treated accordingly. Nasal infections often yield to sulphapyridine snuff (Boissard and Fry 1942, 1944).

Active Immunization against Scarlet Fever and Passive Protection with Serum.

The reagent used for active immunization is a broth filtrate of a culture of a strain of *Str. pyogenes* containing the erythrogenic toxin. This toxin is not converted into toxoid before use. Though some observers (see Veldee 1931, 1933) have reported favourably on the immunizing value of a formol toxoid, similar to that employed in diphtheria immunization, most observers have found such preparations to be relatively inactive (Okell 1932, Dick and Dick 1934). Moreover, unlike diphtheria toxin, the erythrogenic toxin is relatively harmless. The use of the unmodified toxin for immunization rarely leads to any severe local reactions though troublesome reactions are more numerous than in diphtheria immunization. Generalized reactions of the "miniature scarlet fever" type can be avoided by decreasing the initial dose, and working it up very gradually, in those subjects whose reaction to the Dick test shows them to be unusually susceptible.

From our knowledge of the pathogenesis of the disease we should expect that immunization with the erythrogenic toxin would produce an effective immunity against that part of the total scarlatinal syndrome to which it gives rise—the characteristic rash and probably many of the other toxic symptoms. We should not expect any antibacterial immunity. There is no evidence to suggest that the filtrate injected contains an effective dose of bacterial antigen; and, even if it did, the resulting increase in resistance would only be operative against a single antigenic type of hæmolytic streptococcus, while a variety of types may give rise to typical scarlet fever. There is therefore no strong reason to suppose that this

method of immunization will protect against the local proliferation of hæmolytic streptococci in the throat, or their possible spread to other regions; though it might have such an effect if the erythrogenic toxin played a part in damaging the tissues and allowing the streptococci to proliferate.

Extensive field trials have been made and the results are in general accord with expectation, though it seems doubtful whether the immunity induced is as effective as that obtained in immunization against diphtheria.

It would appear (Benson 1928) that the total dose of toxin required to induce immunity may be relatively large—20,000 skin test doses. For persons who give mildly positive Dick reactions 1,000 skin test doses usually form a safe initial dose, but in those who give a vivid and extensive Dick reaction it is wiser to commence with the injection of 500 skin test doses, or even less. Injections may then be given at weekly intervals, increasing the dose 2 to 5 times at each successive injection until a total of 20,000 skin test doses has been given in the course of 3 to 4 weeks. Dick and Dick (1929) have recommended even larger doses, commencing with 500 and working up to 80,000 to 100,000 skin test doses. Kolchin and Klein (1941), immunizing a small series of nurses, found it necessary in order to bring about conversion from the Dick-positive to the Dick-negative state, to use from 9 to 19 injections totalling from 20,000 to 338,000 skin test doses (see also Veldee 1937, 1938, Toomey 1941).

The evidence with regard to the proportion of susceptibles that can be rendered Dick-immune by active immunization is less extensive and less concordant than that available in the case of antidiphtheria immunization. It has been the experience of many observers that the proportion of cases in which a Dick-positive is converted into a Dick-negative reactor is lower and the relapse rate higher, than the corresponding figures for the change in the Schick reaction induced by diphtheria immunization (see Heller 1927, Toyoda *et al.* 1929, Okell 1932).

The records of the incidence of scarlet fever in the immunized and non-immunized are as yet too few to afford a safe basis for any final conclusion as to the effectiveness of the procedure under different conditions; but they clearly suggest that it has considerable value. Toyoda and others (1929) record a scarlet fever incidence of 1 per 1,000 among fully immunized persons, 18·1 per 1,000 among those partially immunized, and 62·5 per 1,000 among non-immunized controls. Similar favourable results in various communities have been reported by Platou (1934) Henry (1935), Krumbiegel (1938), Little (1939), Wartiovaara (1939) and Veldee and his colleagues (1941); the scarlet-fever incidence rates in the non-immunized vary from 4 to 14 times as great as those in the immunized. As in diphtheria immunization, the most significant results have been reported from fever hospitals or other institutions in which the risk of contracting scarlet fever is unusually high.

Benson (1928) records the effect of Dick-testing and immunization on the incidence of scarlet fever among the nursing staff of the Edinburgh City Fever Hospital. From 1919 to 1925, the incidence of scarlet fever fluctuated between 4·82 and 10·27 per cent. Immunization was started in October 1925; in 1926 the incidence was 3·52 per cent. and in 1927 it was 0·67 per cent. The figures for 1928–31, as given in the Annual Reports of the Medical Officer of Health for Edinburgh, show that the very low incidence of scarlet fever has been maintained.

Dick and Dick (1929), summarizing their records, state that among 11,584 immunized persons in institutions where scarlet fever was epidemic, no case of scarlet fever occurred, and that of 1,191 nurses or interns immunized before commencing work in fever hospitals none contracted the disease.

In a group of nurses aged 18–25 years, Cruickshank (1936) found the percentage incidence of scarlet fever to be 0·0 in the naturally Dick-negative, 2·8 in nurses Dick-negative by immunization, 15·0 in nurses who were positive after immunization, and 25·0 in nurses who were originally positive but were not immunized.

It may be noted that the experience of active immunization in man is in general accord with the view that the protection afforded is less effective against the invasive than against the toxæmic effects of haemolytic streptococcal infection. Thus Kinloch and others (1927) note an increase in the frequency of streptococcal tonsillitis among the nursing staff of a fever hospital after its immunization, suggesting that the typical scarlatinal syndrome had been replaced by an infection confined to the throat. Harries (1927) notes a similar fact; he records a slight diminution in the incidence of scarlet fever among the staff after immunization; but the diminution was by no means so striking as the much greater decrease in the incidence of scarlet fever among the staff over the same period (see also Place 1928).

In practice, owing partly to the difficulty of giving five injections, partly to the severe clinical reactions that follow in some subjects, and partly to the absence of protection conferred against infection as distinct from toxæmia, the use of active immunization is very limited. Its chief value is for nurses in fever hospitals, for some children's institutions, and for countries in which the death rate from toxic scarlet fever is high.

Inoculation of contacts with antitoxic serum affords passive protection for 2 to 3 weeks, and may be used in sick or debilitated children, or for other special reasons, when the risk of repeated exposure is negligible.

The Treatment of Scarlet Fever.

Antitoxic Sera.—Clearly, the demonstration that a high-titre antitoxic serum can be obtained by immunizing a horse against erythrogenic toxin raises the question of the value of such antisera in the treatment of the disease in man.

It seems reasonable to suppose that a specific antitoxic serum will exert an effect on those manifestations of scarlet fever that are directly toxic in origin. We might expect a saving of life in severe toxæmic cases, a diminution in the rash and a more rapid subsidence of the fever in the milder type of infection. Whether the serum exerts an indirect effect on the bacterial invasion, by lifting the burden of toxæmia from the body and thereby improving its antibacterial defences, it is difficult to say.

Figures in regard to death or recovery are not easy to obtain because the prevalent type of scarlet fever is mild and the case fatality low. Such figures as are available support the view that there is a significant saving of life in severe toxæmic cases when these occur.

Toyoda and his colleagues (1929) record 8 deaths in 33 serum-treated cases of severe scarlet fever against 15 deaths in 33 untreated cases of the same order of severity; and, so far as data with regard to death or recovery are forthcoming, other records are in general conformity with these observations. Thus Mersol (1929), during an epidemic of scarlet fever in Jugoslavia associated with a high case-fatality rate, records 4 deaths among 117 serum-treated patients (3·4 per cent.) as against 84 deaths among 377 untreated patients (22·3 per cent.).

In regard to the diminution in severity of the rash, the subsidence of fever, and the general alleviation of toxic symptoms, the consensus of opinion clearly supports the view that antiscarlatinal serum has a beneficial effect (see Benson and Maciver 1926, Harries 1927, Discussion 1927, Kinloch and others 1927, Husler 1927, Lenthe 1927, Eley 1928, Scott 1928, Bröcker 1928, Friedemann and Deicher 1928, Toyoda and others 1929, Veldee and others 1931). It should be noted that Veldee and his collaborators, almost alone among those who have reported on this point, failed to demonstrate any significant effect on the temperature although there was a striking effect on the rash.

[illegible] above suggest that anti- [illegible] the frequency of complications; but there are a [illegible]

Hewitt 1927 [illegible] with antitoxin, and 1,190 untreated controls. [illegible] admissions in order to obtain a random [illegible] 15 cases with complications, among the [illegible] not entirely accounted for by the different [illegible] in the treated. Veldee and others 1931 [illegible] 112 serum-treated patients and 84 controls, the allocation [illegible] serum groups again being by alternation of admission. The difference in the frequency of complications was striking, that in the control group [illegible] cervical adenitis, 19·5 per cent. as against 0·4 per cent.: otitis [illegible] 17·4 per cent. as against 7·3 per cent.: suppurative otitis, 7·3 per cent. as against 3·6 per cent. and so on. Those complications that are probably due to toxæmic rather than invasive processes showed the same wide differences—nephritis, 12·2 per cent. in the controls as against 0·0 per cent. in the treated: arthritis, 6·1 per cent. as against 0·0 per cent. Burke 1933, 1936, also has produced striking evidence of the efficacy of antitoxin in reducing not only the death rate, but the incidence of complications. From a large, carefully controlled series of observations he concludes that the intravenous or intraperitoneal administration of 10–20 ml. of antitoxin in a single dose reduces the incidence of otitis media by one-third and of nephritis by one-seventh. It is noteworthy that by intramuscular antitoxin he could produce no statistically significant reduction in the incidence of complications (but see Ronaldson 1937). Neukirch, Zahle and Baumgarten (1943), giving antitoxin early in the disease to all cases irrespective of the degree of toxæmia, reduced the complication rates to a small extent as compared with control cases, but found that the benefit was outweighed by serum sickness, which occurred in 64 per cent. of the patients. In this connection it should be noted that Chandler and Hartshorn (1933) observed in four scarlet fever patients treated with antitoxin the coincidence of a streptococcal bacteræmia with the onset of serum sickness, and suggested that the serum sickness might have contributed to the exacerbation of the infection (see also Burn, Chandler and Hartshorn 1934).

Summing up, we may say that there is clear evidence that antitoxic serum has a significant therapeutic effect on the toxic manifestations of scarlet fever, and suggestive evidence that it may—contrary to our *a priori* expectations—lessen the frequency of those complications that are due to the invasive action of the streptococci.

In practice, it is advisable to give antitoxic serum—preferably of the refined protein-digested type—to patients nursed in an open ward. In mild cases it should be injected intramuscularly, in severe cases intravenously. Though it may protect to some extent against complications, it has no effect once these have occurred. It may be noted that some workers prefer convalescent serum in the treatment of scarlet fever, on the ground that it probably has antibacterial as well as antitoxic properties (see Gordon 1933, Platou, Dwan and Hoyt 1941).

The Standardization of Scarlatinal Antitoxin.—As in the case of all other antisera, the standard of reference is an arbitrarily selected sample of serum. It happens that the unit of this serum was defined as 10 times the amount that, in the skin-neutralization test, will protect against the "test dose" of toxin; while the "test dose" is defined as five "skin test doses," and a "skin test dose" as the least amount of toxin that, in a majority of susceptible persons, gives rise to a local skin reaction of not less than 10 mm. in diameter (see Dyer 1928). But there is nothing exact or binding about this definition. The Standard American serum was adopted

by the Standardization Committee of the [illegible] national Standard and Unit [illegible]

The great difficulty, which may [illegible] of any suitable experimental animal [illegible] titrated.

Kirkbride and Wheeler 1926 [illegible] and Ando and Kuranchi 1930 in white pigs; [illegible] generally confirmed.

Until recently the most hopeful approach [illegible] by Parish and Okell (1927). Rabbits are [illegible] the serum under test, and, 4 to 6 hours later, with [illegible] virulent strain of a hæmolytic streptococcus. The [illegible] the acute septicæmic death that occurs in control. [illegible] the antitoxin die eventually of a subacute streptococcal [illegible], pericarditis, etc.; but death seldom occurs before the 6th day, and this is [illegible] end-point (see also O'Brien, Okell and Parish 1929).

In 1930, however, Fraser and Plummer described a method of titrating [illegible] and antitoxin in the skin of Chinchilla rabbits; and further experience with this test suggests that, with certain modifications, it gives results as accurate as those obtained in the human skin, or by the method of Parish and Okell (see Kolmer *et al.* 1933, Plummer 1934, Buttle and Lowdon 1935). Veldee (1932) and Malcolm and Wyman (1937) developed a similar test, using the ear of the rabbit. Many attempts have been made to titrate the erythrotoxin by a constant-antigen flocculation method analogous to the Ramon titration of diphtheria toxin. More recently, successful *in vitro* titrations of erythrogenic toxin, tallying with those in man and animals, have been made, using solutions of toxin containing over 50,000 skin test doses (Rane and Wyman 1937, Bunney and Kneipel 1941, Hottle and Pappenheimer 1941, Proom 1941).

Convalescent Serum.—The use of convalescent serum in the treatment of scarlet fever has the obvious advantage that to a large extent serum reactions are avoided (see, for example, Fox 1937). Large-scale tests of pooled convalescent serum indicate that it may be at least as effective as antitoxin in reducing both mortality and complication rates (Fox and Hardgrove 1937). Top and Young (1939, 1941), who recommend its use in the septic forms of scarlet fever, found that a pooled serum containing 60 antitoxic units per ml. was as effective as a horse antitoxin containing 6000 units per ml., and concluded that convalescent serum owed its efficacy to antibacterial as well as to antitoxic antibodies. Moore and Thalhimer (1939) tested convalescent sera for antitoxic and antibacterial activity. The antitoxin content averaged 3·3 units per ml. The bactericidal power, measured on four antigenically different strains of Group A streptococci, was, when present, to some extent strain-specific. Platou, Dwan and Hoyt (1941) tested the bactericidal power of whole blood, and demonstrated that convalescent bloods were more bactericidal than normal bloods, and that the effect was independent of antitoxic immunity. These results support the suggestion of an antibacterial action. If the action is type-specific, then only pooled polyvalent sera, or type-specific convalescent sera, will be efficacious in the treatment of scarlet fever.

Chemotherapy.—In the treatment of scarlet fever cases sulphonamides appear to be of little value except for dealing with complications. It is true that the routine use in all patients has been recommended by some workers (Neukirch *et al.* 1943); but there is little evidence to show that they influence the course of the disease, and if protection is to be afforded against both early and late complications

average resistance of the various communities affected can have differed so widely as to account for the marked difference in clinical manifestations.

We should not, in such a conception of *Str. pyogenes* infections, interpret the term "toxigenicity" too literally. It is very probable that invasiveness and perhaps the capacity to multiply freely in the tissues at the original foci of infection are at least equally involved. The determining factor will be the ability of any given strain to produce toxin plentifully and rapidly in the tissues, and this involves many factors that are not concerned in the production of toxin by an organism growing under optimal cultural conditions in the laboratory. We may recall the fact that the undoubted differences in virulence between the *gravis*, *intermedius* and *mitis* types of the diphtheria bacillus are not closely paralleled by differences in toxigenicity as judged by growth *in vitro*.

It may, perhaps, be added that the studies of Griffith and his colleagues on epidemics of hæmolytic streptococcal infection, particularly in schools, supply some of the strongest evidence in support of the view that there exist, within any given pathogenic bacterial species, particular "epidemic strains" endowed with a heightened power of spreading naturally among the population at risk. Reference to Chapter 56 will show that this view is also supported by the results obtained in experimental epidemics.

Mention has already been made under scarlet fever of the occasional prolonged infectivity of convalescent carriers having enlarged unhealthy tonsils. In some of these, throat swabs may fail to detect hæmolytic streptococci. *Str. pyogenes* can usually be isolated from about 50 per cent. of excised tonsils (Elliott 1939, Keogh *et al.* 1939*b*, Macdonald *et al.* 1940). Rantz (1941) records figures of 32·7 per cent. from the tonsils after removal, but of only 16·4 per cent. from throat swabs before tonsillectomy.

In the prevention of tonsillitis *chemoprophylaxis* with the sulphonamide group of drugs is now being tried. Too little information is yet available on which to assess the value of this method, but large-scale observations in the United States army and navy suggest that streptococcal infections of the upper respiratory tract, together with complications such as otitis media, may be considerably reduced in incidence by the daily administration of 1 gm. of sulphadiazine (Holbrook 1944, Coburn 1944*b*). The conditions under which these trials were made, however, were not altogether satisfactory, and the experience so far gained in this country is not reassuring. Reports on the use of sulphonamides in the treatment of acute tonsillitis are conflicting, but no striking benefit seems to result from their administration. The response to penicillin, both clinically and bacteriologically, is said to be rapid, but relapse is common unless treatment is maintained for at least 6 days; even so, complications cannot be entirely prevented (Plummer *et al.* 1945).

Erysipelas

This classical example of acute streptococcal infection may, for our present purposes, be shortly dismissed. As an experimental disease it has been discussed in some detail in Chapter 53, in connection with the general problem of local immunity. There is evidence (see for example, Keefer and Spink 1936) that in some cases the attack is preceded by an infection of the throat or upper respiratory tract, and it is noteworthy that in 10 of 37 patients with erysipelas, de Waal (1941) found the same type of *Str. pyogenes* in the skin lesion and in the throat; but it is not clear whether the streptococcus, if it is the cause of the erysipelas, reaches

... usually and sets up 'traumatic erysipelas, or by an internal route, and ... an apparently "idiopathic" erysipelas.

The interest of erysipelas, in relation to the question of streptococcal immunity in general and scarlatinal immunity in particular, lies in the well-attested fact that a single attack of the disease confers no protection against subsequent infection; indeed, some persons appear to possess a marked predisposition to the disease, and suffer from many attacks throughout their lives—usually in the same skin area. The striking contrast in this respect, between erysipelas and scarlet fever, suggests an essential difference in the mechanism of infection and resistance, and it would seem reasonable to accept, as a purely provisional hypothesis, the view that the antitoxic immunity, which is the essential factor in resistance to scarlet fever, is relatively ineffective as a protection against the invasion of the skin by *Str. pyogenes*, which is the essential feature of erysipelas.

This does not of course involve the view that the erythrogenic toxin plays no part in erysipelas: indeed, there are several reasons for believing that it may be responsible for certain features of the disease (see Okell 1932). It means only that a degree of antitoxic immunity that will protect against scarlet fever will not protect against an erysipelatous infection of the skin.

Puerperal Fever

In discussing the problem of puerperal infection it has become customary, among those who are concerned with this problem from the clinical aspect, to adopt some arbitrary standard of pyrexia and to include in the febrile category all cases which show a rise in temperature beyond this limit of duration. Such a classification, however useful it may be from the clinical point of view, can have little relation to aetiological factors; and it is probable that the milder degrees of puerperal pyrexia include a miscellany of bacterial infections, which cannot, at the moment, be classified on any bacteriological basis.

As a cause of puerperal septicæmia, however, there can be no doubt that the hæmolytic streptococcus holds a pre-eminent position (London and N. England Committee 1925, Fitzgibbon and Bigger 1925, Colebrook, L., 1926, Kinloch *et al.* 1928, Colebrook, Dora C., 1935, and others). Colebrook, D. C. (1935), for instance, in reviewing the results recorded by various workers, notes that among the fatal cases of puerperal fever the proportion due to infection with hæmolytic streptococci varied from 68 to 96 per cent. The majority of these streptococci belong to Group A, though a small proportion of puerperal infections are associated with Groups B, C, D and G, and very rarely, some of the remaining groups (Lancefield and Hare 1935, Gardner 1939, Chatterjee and Mitter 1941). Infection by hæmolytic streptococci other than Group A is not usually severe, though among these milder infections a number of authors have noted severe and sometimes fatal cases of septicæmia, often associated with infective endocarditis, following puerperal or post-abortion infection by streptococci of Groups B, G and rarely C (Colebrook and Purdie 1937, Fry 1938, Macdonald 1939, Hill and Butler 1940, Rosenthal and Stone 1940, Ramsay and Gillespie 1941).

Since the severe infections are due to *Str. pyogenes*, we must consider the part played by the erythrogenic toxin in the genesis of the infection, and by antitoxic immunity in resistance to it. If an antitoxic immunity of this type conferred any increased resistance to puerperal infection with hæmolytic streptococci we might reasonably hope to induce a significant decrease in maternal mortality by antitoxic immunization, carried out during

pregnancy. In view, however, of our general knowledge of the role of [illegible] antibacterial immunity, we should [illegible] to afford any significant protection against an invasive [illegible] leading to septicæmia; and the facts are in [illegible] Colebrook and others (1930), Stent (1930) and Bird [illegible] that severe puerperal infections are just as common in [illegible] as in those who react positively. Moreover, Kenny and Colebrook (1927) found that none of 19 women who were Dick-positive in the early stages of pregnancy [illegible] Dick-negative as a result of that infection. Clearly [illegible] genic toxin from the lesions in the genital tract. Very [illegible] panied by a scarlatiniform rash, and it is noteworthy that in [illegible], Kenny and Colebrook found a powerful erythrogenic toxin in the exudate from the genital tract.

It does not of course follow that the other toxins produced by haemolytic streptococci, the hæmolysin, leucocidin and so on (see Chapter 24) and the corresponding antibodies, play no significant part in puerperal infection; but it may be stated that the balance of evidence at present available is in favour of the view that the decisive factor in attack is the invasiveness of the organism, and that defence depends, in the main, on an antibacterial immunity that is type-specific. We shall return to this question in relation to prophylaxis and treatment.

Sources of Infection.—The most important question from this point of view is as to whether the majority of puerperal infections with haemolytic streptococci are intrinsic or extrinsic. These terms are usually employed to differentiate between those cases in which the hæmolytic streptococcus is present in the female genital passages before labour, and those in which it is introduced from without during labour or the puerperium. The problem at issue therefore narrows down to the presence or absence of the hæmolytic streptococcus in the cervix or vagina during the later periods of pregnancy. If it is frequently present under normal conditions, we should lay particular stress on host susceptibility, and on the extent of tissue injury during labour, as factors determining the occurrence of puerperal fever: if it is usually absent, we should regard infection from without as the essential factor, and stress the vital importance of asepsis and antisepsis in handling maternity cases.

Fromme (1908) found streptococci in the vaginal secretions of 46 of 136 pregnant women, but none was hæmolytic. On the other hand he cultivated hæmolytic streptococci from almost every case of severe infection during the puerperium. Lüdke and Polano (1909) found no hæmolytic streptococci in 30 cases during a normal puerperium. Kanter and Pilot (1924) examined 96 cases during pregnancy, and found hæmolytic streptococci in one case only. Lockhart (1925) in a careful study of 100 cases, during which swabs were taken before and after labour, found hæmolytic streptococci in one case only before labour occurred, though streptococci of other types were frequent. One other case showed the presence of this organism in a swab taken immediately after labour; and in four other cases, in each of which a single swab before labour and two taken in the first few days of the puerperium were negative, a copious growth of hæmolytic streptococci was obtained from a third swab, taken immediately the temperature began to rise. Taylor and Wright (1930) isolated 32 strains of hæmolytic streptococci from vaginal swabs taken from 1,123 pregnant women immediately after labour; only 18 (1·6 per cent.) could be classified as *Str. pyogenes* on the basis of fermentation reactions.

It may then be stated with some confidence that hæmolytic streptococci are very infrequent in the genital passages during pregnancy, being present in something under 3 per cent. of cases. In the early days of the puerperium they are rather more frequent, being found in about 5 to 6 per cent. of all cases (see Hare

... the observation of these cases showed that those women who were harbouring hæmolytic streptococci in their genital passages before labour were particularly liable to suffer from puerperal fever the hypothesis of intrinsic infection would receive strong support; but this is not so. There is general agreement that the great majority of them pass through a perfectly normal puerperium and that this is also true of a high proportion of those women from whose genital passages hæmolytic streptococci are isolated during the puerperium itself. The reason for the harmlessness of these streptococci is clear. Few of them are *Str. pyogenes.*

Hare and Colebrook (1934), for example, found only 2 of 52 strains to be *Str. pyogenes* according to fermentation reactions; about half gave the reactions of *Str. agalactiæ* (Chapter 24). Lancefield and Hare (1935) found one Group A strain among 65 vaginal strains isolated during an afebrile puerperium, and none among 13 strains isolated before labour.

It may be added that Colebrook, Maxted and Johns (1935) failed to detect *Str. pyogenes* on the perineal or peri-anal skin of 160 women attending an antenatal department, and that Hare and Maxted (1935) failed to isolate *Str. pyogenes* from the fæces of 100 normal women during the first stage of labour.

There can then be very little doubt that *Str. pyogenes* is not a very frequent inhabitant of the normal genital passages either before or after labour. In Lancefield and Hare's series, for instance, the 13 strains of hæmolytic streptococci isolated before labour were obtained as the result of swabbing 855 women, and none of them was *Str. pyogenes.* The hypothesis of intrinsic puerperal infection receives very little support from such studies as these.

If we accept the view that infection is usually extrinsic in origin it is clearly of importance to determine its source. An obvious working hypothesis is that the hæmolytic streptococci are derived from those in attendance on the patient, or at least in her immediate entourage. Until recent years it was extremely difficult to test this hypothesis by observation. The normal carrier rates quoted earlier in this chapter will show that, if 5 to 10 persons have come into contact with a patient during labour in the early days of the puerperium, there is a very good chance of one or other of them carrying a hæmolytic streptococcus in the throat. It would be quite unjustifiable to assume on such a basis that the carrier in question had infected any particular case of puerperal fever.

The division of *Str. pyogenes* into 40 or more distinct serological types has, however, entirely altered the position.

Taking an average figure of 6 per cent. for the normal carrier rate of *Str. pyogenes* in the throat (see above), we should expect about one person in seventeen who came into contact with a parturient woman to be a possible source of danger. But if this person may be harbouring any one of the 40 or more different types, and the patient may also be suffering from infection with any one of these types, the odds against the type isolated from the contact being identical with the type isolated from the patient become very high indeed, unless the patient has derived her infection from the contact, or *vice versa.* We cannot multiply 40 by 40 to get the exact odds, because that would assume that the carrier rate for each type of streptococcus was equal, which is almost certainly not the case; but the odds are certainly high enough for an established identity of type to be significant.

Two series of observations are on record in which this method has been applied, using the technique of agglutination and agglutinin absorption for the antigenic

analysis of the strains isolated. Smith (1931, 1933) was able to show that, in 39 of 49 cases of puerperal fever due to *Str. pyogenes* a strain identical with that derived from the patient was also found in the throat or nose of the midwife, or doctor, or some other person in attendance on the patient or, more rarely, in the throat or nose of the patient herself. In 8 cases only the latter event occurred in 8 cases as opposed to 31 cases in which it was the probable source of infection.

Dora Colebrook (1935) has recorded a very careful and detailed study on similar lines, involving the examination of 60 cases of puerperal fever and their contacts. In 38·1 per cent. of these cases a haemolytic streptococcus antigenically identical with that derived from the blood or uterine discharges of the patient was also isolated from the patient's throat or nose. In 57·1 per cent. of the cases a strain antigenically identical with that causing the infection in the patient was isolated from the throat or nose of one or more persons in contact with the patient. In a proportion of these cases (22·2 per cent.) both the patient and a contact were carrying a strain identical with the infecting strain. Thus in 73 per cent. of the cases a strain identical with the infecting strain was isolated either from a contact or from a patient or from both.

We may conclude that, in a very high proportion of cases, the most probable source of uterine infection with *Str. pyogenes* during labour and the puerperium is from the throat or nose of some person in contact with the patient, or from the throat or nose of the patient herself. We must regard this transfer from outside sources to the genital passages as probable rather than certain, because we cannot exclude the possibility that transfer sometimes occurs in the reverse direction.

In regard to the mode of transference an observation of Colebrook, Maxted and Johns (1935) is of considerable interest. They were able to isolate *Str. pyogenes* from the skin of the hand in 7 of 181 normal persons (3·8 per cent.). Of 248 normal persons Hare (1941) found only one (0·4 per cent.) to be carrying Group A streptococci, and our colleague, Dr. R. E. O. Williams, only 4 (0·5 per cent.) of 875 persons. Taking the normal carrier rate in the throat as about 6 per cent., and regarding this as the most probable source of hæmolytic streptococci found on the hands, an obvious alternative is provided to direct droplet infection.

Prophylaxis.—If an effective method of active immunization were available the conditions for applying it would be peculiarly favourable, since we should be protecting against a risk occurring at a predictable time, with several months at our disposal during which immunity could be induced. Unfortunately no such method is at our disposal, nor is the immediate outlook hopeful. An antitoxic immunity, if effective, in this disease, would confer protection against all types of *Str. pyogenes*, since all form the same toxins. As we have seen, however, there is no evidence that such an immunity confers resistance against the invasive powers of the streptococcus. Such antibacterial immunity as we can induce by the injection of a bacterial vaccine, as Stamp (1936) has shown experimentally, will be type-specific, and it would therefore be necessary to include in our vaccine all the antigenic types that are responsible for puerperal infection. When we know more than we do now in regard to the actual frequency of these various types in puerperal fever it may be possible to prepare a vaccine that will protect against the types that are most often met with; but our present data contain no indications that any particular type, or any small group of types, will be found to cover a large proportion of cases.

In the absence of an effective measure of active immunization we are forced to rely, in the main, on methods designed to prevent *Str. pyogenes* gaining access to the genital passages of parturient women by droplets, dust-particles (see White 1936) and by the numerous possible methods of direct and indirect contact. Some of the lines along which such methods should be developed are sufficiently obvious from the observations outlined in this chapter. For further details see Report (1944).

Reference may be made to Chapter 54 for a description of the attempts that have been made to increase the general resistance of pregnant women by adding Vitamin A to the diet.

Serum Treatment.—It is obvious that the factors that apply in prophylactic active immunization apply also to passive immunization in an established case by the injection of a specific antiserum. We should not expect that an antiscarlatinal serum, the principal effect of which is to neutralize the erythrogenic toxin, would confer any appreciable benefit, and in fact it does not do so. Nor is there any immunological reason to suppose that any of the ordinary antistreptococcal sera on the market will prove effective. We cannot, of course, exclude the possibility that antihæmolysin, antileucocidin, or antifibrinolysin, may exert some beneficial effect; but we have no evidence that they will protect against the invasive action of *Str. pyogenes*, nor are the ordinary antisera standardized as to their content in these antibodies. If we desire an antibacterial effect we must ensure that the antibody in our serum corresponds to the surface antigen of our infecting bacterium, as we do in the treatment of lobar pneumonia (see Chapter 74); and this we cannot do. The results of adequate clinical trials are as unsatisfactory as these considerations would lead us to expect (see Colebrook, L., 1935, Kenny and Colebrook, L. 1937).

At present, then, there is no method of serum treatment in puerperal fever that is founded on a scientific basis. When we have at our disposal type-specific antibacterial sera, can ascertain the type of the infecting streptococcus, and select the corresponding antiserum for treatment, we shall be in a position to carry out clinical trials with some hope of success.

The Rôle of Anaerobic Streptococci in Puerperal Fever.—Although we are concerned in this chapter with diseases caused by hæmolytic streptococci, it will be convenient to complete our summary of the bacteriological aspects of puerperal fever by a brief discussion of the part played by other organisms.

So far as severe and fatal infections are concerned, the organisms most frequently isolated, apart from *Str. pyogenes*, are the anaerobic streptococci described in Chapter 24.

Colebrook and Hare (1933), for instance, record that, among 100 positive blood cultures from a series of unselected cases of severe puerperal infections 60 yielded *Str. pyogenes*, 38 anaerobic streptococci, and 2 both types of organism. Although the case fatality of the bacteræmic type of puerperal fever due to anaerobic streptococci is high—about 40 per cent. (Colebrook, L., 1930)—the infections are of a less fulminating type than those due to *Str. pyogenes*. It seems probable, in view of the figures given above for the observed proportions of *Str. pyogenes* infections in different samples of fatal cases of puerperal infection, that the frequency of anaerobic streptococcal infections observed by Colebrook and Hare at Queen Charlotte's Hospital will prove to be rather above the average figure; but that these organisms rank second only to *Str. pyogenes* as a bacterial cause of maternal mortality there

can be no question. A point of some interest (see Colebrook and Hare 1933) is that mixed infections are relatively common, two or more different types of anaerobic streptococci being isolated from the blood in over 50 per cent. of the cases. The occurrence of these mixed infections has also been noted by Brown (1932).

The epidemiology of these anaerobic streptococcal infections forms an interesting contrast to that of puerperal fever caused by *Str. pyogenes*. It has been shown by many observers (see Natvig 1905, Wegelius 1909, Roskowsky 1912, Sonke and Brown 1932, White 1933) that anaerobic streptococci form part of the normal flora of the female genital tract; and the observations of White (1933) suggest that this may be their principal natural habitat. In this case therefore there can be little doubt that puerperal infection is largely intrinsic. (For other references in relation to anaerobic streptococci and their rôle in puerperal fever, see Chapter 24.

Other Types of Puerperal Infection.—It remains to add that a few cases have been reported in which a fatal pyæmic infection due to *Staph. aureus* has developed during the puerperium; but these are rarities.

In regard to the less severe and fatal types of puerperal infection, which are for the most part localized to the pelvis, a variety of bacteria may be responsible. Many cases are due to a localized infection with *Bact. coli*, and these are not infrequently associated with an infection of the urinary tract. Another group of cases are due to pelvic infections with the gonococcus; and another group, especially after abortion, to infections with *Cl. welchii* (see Butler 1941).

Other Infections due to Hæmolytic Streptococci.

Cellulitis and other forms of suppuration due to *Str. pyogenes* are discussed in Chapter 67, the part played by this organism in acute respiratory infections is considered in Chapter 74, and its relation to acute rheumatism in Chapter 68.

The Use of Specific Antisera in Infections with Str. pyogenes other than Scarlet Fever and Puerperal Fever.

The considerations outlined above in the discussion of the use of antistreptococcal sera in the treatment of puerperal fever clearly apply to all other infections with *Str. pyogenes*. With the single exception of scarlet fever, and the usefulness in that disease of a serum containing the specific antitoxin that neutralizes the erythrogenic toxin, there is no immunological evidence that any of the available antisera is likely to exert a specific curative effect.

Chemotherapy in Infections with Str. pyogenes.

It has already been mentioned that sulphonamide therapy finds little place in scarlet fever apart from the treatment of complications. The same holds true of tonsillitis, though there is a suggestion that they may be of use in this disease (see Freis 1944). It should, however, be used at the first sign of invasion of other tissues than the nasopharynx. Sulphonamides, particularly sulphapyridine and sulphadiazine, are of proved value in the treatment of erysipelas, cellulitis and particularly puerperal sepsis of streptococcal origin. It is too early yet to say what part penicillin will play in future in the routine therapy of the diseases considered in this chapter; but already it has established itself as a potent means of combating streptococcal septicæmia.

CHAPTER 67

PYOGENIC AND WOUND INFECTIONS

We have dealt in other chapters with many diseases which are associated with acute inflammatory or suppurative conditions in various parts of the body. There remain a number of infections which are characterized by the local formation of pus, by a spreading inflammatory reaction, associated with the formation of a purulent exudate, or by a septicæmic or pyæmic invasion of the blood stream. The bacteriology of some of the more important of these conditions is briefly discussed in the present chapter. It should be emphasized that the separation of bacterial infections, or of the bacteria which cause them, into pyogenic and non-pyogenic groups is largely arbitrary, and depends on the observation of the relative frequency of frankly suppurative lesions, among all those reactions which together characterize the association between a particular bacterial parasite and a particular animal host, the host species usually being man. It is quite easy to select some bacterial species, such as *Staph. aureus* or *Str. pyogenes*, as frankly pyogenic, and some others, such as *Myco. lepræ*, *C. diphtheriæ*, or *Cl. tetani* as non-pyogenic, in the usual sense; but there are very many pathogenic bacteria which cannot be assigned definitely to one class or the other. The reaction of acute inflammation, associated with the formation of a serous, or sero-fibrinous exudate, and with the diapedesis and accumulation of polymorphonuclear cells, is a fundamental defence mechanism, which is brought into play in response to a great variety of stimuli; and there are few bacterial species which are not pyogenic, in the sense that their presence may call forth this particular reaction in certain situations, and in certain circumstances. The characteristic reaction to the tubercle bacillus, for instance, takes the form of a non-suppurative granuloma, with giant cell formation and caseation; but in the pleural cavity, in the meninges, or in the urinary bladder, the same bacillus may cause the formation of an inflammatory exudate containing a considerable proportion of polymorphonuclear cells. Similarly, the typhoid bacillus is not, in the usual sense, a pyogenic organism; but it may cause a suppurative cholecystitis. All we can do, in discussing pyogenic infections in general, is to indicate in a few instances the bacteria which are most commonly associated with these conditions.

Septicæmia.

Bacteræmia, in the sense of the mere presence of bacteria in the blood stream, has been described in several earlier chapters. Septicæmia is here used as a designation for a clinical syndrome associated with a severe bacteræmic infection. We may note that, among those organisms which tend to produce pyogenic lesions terminating in a fatal septicæmia, *Str. pyogenes* is by far the most important. The pneumococcus, belonging to the same genus, is a frequent cause of the same type of infection, either

invading the blood stream directly from the lung, or from some suppurative focus such as an empyema. *Staph. aureus* may produce a purely septicæmic infection, following a localized infection, or an acute lymphangitis, but the generalization of a staphylococcal infection more commonly takes the form which is described in the following section. The occurrence of a transitory invasion of the blood stream by streptococci of the viridans type in cases of oral sepsis will be referred to in Chapter 68 (p. 1515). Attention may be drawn to the occurrence of septicæmia due to the non-sporing anaerobe *Fusiformus fusiformis*. This type is particularly liable to follow anginal infections, though it sometimes occurs after appendicitis or endometritis (see Chapter 79). Septicæmia due to anaerobic streptococci also occurs. Infections by anærobic bacteria are liable to be overlooked because diagnostic culture of the blood is seldom made anaerobically; and in the same way infections with bacteria that need an excess of carbon dioxide for growth (Chapter 3) will not be discovered unless a sample of blood is cultivated in air containing 5–10 per cent. CO_2 (see Khairat 1940).

The great majority of bacteria which produce suppurative lesions may on occasion give rise to a secondary septicæmia; and in almost all fatal cases of this type such an invasion of the blood stream occurs during the terminal stages of the disease. Thus a septicæmia occurs during the later stages of meningococcal meningitis, in cases of acute peritonitis, in rare cases of acute gonococcal infection, and so on. It is sometimes asserted that in septicæmia organisms are multiplying in the blood, while in bacteræmia they are derived from infected tissues. Such a distinction clearly cannot be drawn from the results of blood culture; it rests indeed on dubious clinical inference. The observation that a large and rapid increase in the number of circulating bacteria sometimes takes place just before death suggests multiplication in the blood stream; but with this exception, the septicæmic phase of any bacterial infection is probably the expression of a rapid and continuous invasion of the blood stream from the tissues, either from a single focus which is active and extensive, or from the multiple foci which have been established earlier in the disease. In the frankly suppurative diseases, in which the primary or secondary foci are accessible to surgical interference, the results of adequate drainage testify to the efficiency of the clearing mechanism of the blood stream, if continuous re-invasion can be prevented.

Pyæmia.

This term is employed clinically to designate a type of generalization the mechanism of which differs, to some extent, from that referred to above. In some bacterial infections, and particularly in the more severe forms of infection with *Staph. aureus*, such as acute osteomyelitis, metastatic abscesses may occur in such situations as the kidney, the brain, or the myocardium. In rare cases of appendicitis, or of other suppurative lesions in the abdominal cavity, multiple abscesses may occur in the liver, in direct relation to the portal vein—a condition known as "portal pyæmia," and usually due to infection with *Bact. coli*. In either case the dissemination appears to depend on the occurrence of a suppurative phlebitis at the site of the primary lesion. This extends directly as a progressive thrombosis; and particles of the infected thrombus, becoming detached, are carried by the blood stream until they reach some situation in which the anatomy of the blood vessels determines their impaction, where they give rise to secondary abscesses.

Staphylococcal Infections of the Skin and Subcutaneous Tissues.

Many of the localized pustular lesions of the skin are caused by staphylococci. The milder forms, such as acne pustules, are usually associated with a white staphylococcus (see Chapter 25). The more severe forms, such as boils or carbuncles, are almost always due to *Staph. aureus*. It may be noted that, in the acne pustule, the white staphylococcus is usually accompanied by the acne bacillus, which Fleming (1909) regards as the primary ætiological agent of the disease. For the isolation of the acne bacillus in the presence of staphylococci penicillin is said to be of value (Craddock 1942).

Infection of the sebaceous follicles in acne, and of the hair-follicles in superficial boils, appears to take place directly from the skin, without trauma. A more serious type of staphylococcal infection sometimes follows an insignificant traumatic infection with a virulent strain of *Staph. aureus*, taking the form of a rapidly spreading lymphangitis, with involvement of the regional lymph glands, and often terminating as an acute septicæmia. *Staph. aureus* may also give rise to suppurative mastitis in nursing mothers and to a form of pemphigus neonatorum in infants; both diseases may at times assume epidemic proportions in maternity homes (see Editorial 1936, Elliott, Gillespie and Holland 1941, Henderson 1943).

Botriomycosis.—In the past the term botriomycosis has been limited mainly to a disease of horses characterized by the occurrence of chronic abscesses in the skin, subcutaneous tissue, udder, spermatic cord, and less often the viscera. Of recent years, however, a disease of cattle and swine referred to as actinomycosis of the udder, has attracted considerable attention (see Magnusson 1928, Albiston 1936). Bacteriological study has rendered it clear that both the disease in the horse and the udder disease in cattle and swine are caused by *Staph. aureus*. There is therefore no longer any justification for calling two ætiologically identical diseases by different names, particularly since the term actinomycosis is applied to a disease of entirely different origin. We propose to use the term botriomycosis to cover all chronic granulomatous infections in animals due to *Staph. aureus*. A word of caution, however, is necessary. In swine, though not in cattle, true actinomycosis of the udder, due to infection with *Actinomyces bovis* or a closely related organism, does occur, and the differential diagnosis between this condition and botriomycosis has to be made by pathological and bacteriological methods. Again, *Staph. aureus* not infrequently gives rise in cows to an acute mastitis; this disease must not be referred to as botriomycosis.

In the horse the abscesses are single or multiple, have thick fibrous walls, and are liable to break down with the production of sinuses and fistulæ containing a gelatinous discharge. On section, the interior of the abscess is seen to consist of soft nodes of granulation tissue situated in a network of fibrous strands. Embedded in the granulation tissue are small yellowish-white granules about the size of a grain of sand. These consist of grape or mulberry-like clusters of Gram-positive micrococci surrounded by a zoogloeal substance. The granules are sometimes referred to as Bollinger's granules, and the organism has been called *M. ascoformans*, though there is little doubt that it is in fact *Staph. aureus*. A similar picture is seen in mammary botriomycosis of swine. In cattle, however, the colonies are surrounded by definite clubs instead of by an undifferentiated mass, and thus bear a close resemblance to true actinomycosis. In all three animals the disease may be reproduced by experimental inoculation of *Staph. aureus* under suitable conditions.

Streptococcal Infections of the Skin and Subcutaneous Tissues.

Erysipelas, an acute spreading infection of the true dermis, has been considered in Chapters 53 and 66.

Impetigo contagiosa, a contagious and sometimes epidemic infection of the superficial layers of the skin characterized by early vesicle formation and subsequently by weeping scabbed lesions, is usually thought to be streptococcal in origin. The evidence, however, in favour of this view is not altogether convincing. Cruickshank (1941) examined 23 cases, and isolated Group A haemolytic streptococci from 15 and *Staph. aureus* from 18 of them. Bigger and Hodgson (1943), who made 230 cultures from 130 cases, found that 97 per cent. of them yielded staphylococci and 32 per cent. *Str. pyogenes*. Staphylococci were present without streptococci in 67 per cent. of cultures, and *Str. pyogenes* without staphylococci in only 2 per cent. The longer the disease lasted, the higher was the proportion yielding streptococci, suggesting that these organisms were secondary invaders. In a later series of 50 cases, *Staph. aureus* was isolated from every patient, and *Str. pyogenes* from only 7 (Bigger and Hodgson 1944). These authors conclude that impetigo is primarily a staphylococcal infection.

Cellulitis is an acute spreading infection of the subcutaneous tissue, characterized by the formation of a sero-purulent, often blood-stained exudate, with no evidence of localization. Rapid lymphatic spread, and septicæmic generalization, are far more frequent than in the case of the localized staphylococcal infections. In very acute infections, such as those which may follow post-mortem wounds, the local manifestations may be minimal, the spread being so rapid that an acutely fatal septicæmia dominates the clinical picture from the first. In these conditions the streptococcus concerned is almost always *Str. pyogenes*.

It may be noted that a comparison of the modal types of staphylococcal and streptococcal infection affords an excellent example of the importance of differences in the biological characters of bacteria, in determining the type of lesion which they produce when they gain access to the tissues.

Mastitis in Cattle.—This important disease can only be touched on briefly here. Those seeking further information are referred to the monograph by Steck (1930) and to the series of papers by Minett and his colleagues in this country (Minett, Stableforth, and Edwards 1929, 1930, 1932, 1933, Minett and Stableforth 1931, Minett 1932, 1935, 1936, 1937, Stableforth 1930, 1932, Edwards 1932, 1933, 1934, 1938, Stableforth, Edwards, and Minett 1935, Report 1941, Watts, 1941, Discussion, 1942), to Klimmer and Haupt (1930) and Seelemann (1932) in Germany, to Rosell (1933) in Canada, to Hucker, Reed and Savage (1937) in the United States, and to Stewart (1937) and Bull, Murnane, Munch-Petersen and MacLean (1940) in Australia.

The disease is very prevalent among milch cows both in Europe and in the United States (see Brigham *et al.* 1929, Hucker *et al.* 1932), and constitutes one of the most serious economic problems confronting the dairy farmer. It is moreover of some public health importance, since occasionally streptococci of a type pathogenic for human beings may be excreted in the milk and give rise to scarlet fever or septic sore throat in those consuming it in the raw condition (see Chapter 93).

The bacteriology of mastitis is varied. Minett, Stableforth, and Edwards (1929), who investigated 113 cases of mastitis, found that 82 were due to streptococci, 21 to *C. pyogenes*, 6 to staphylococci, 3 to coliform bacilli, and 1 to *F. necrophorus*.

Ps. pyocyanea is sometimes responsible (Swett *et al.* 1944). We may briefly consider these different types.

STREPTOCOCCAL MASTITIS.—The streptococci causing mastitis may be divided on cultural, biochemical, and serological grounds into three groups.

Group I streptococci—the typical *Str. agalactiæ* (see Chapter 24)—are responsible for the common condition of chronic mastitis. The incidence of this disease increases with the age of the animal, and is high in cows over 5 years of age. Usually more than one quarter of the udder is attacked. Infection probably occurs through abrasions on the teats or *via* the teat canal, and is spread by the hands of the milker. The condition is very chronic, and it is doubtful whether complete recovery ever occurs.

Group II streptococci give rise usually to acute or subacute mastitis, which is much less common than the chronic form just described. The distinguishing features of Group II streptococci are absence of hæmolysis, reduction of methylene blue in milk, failure to ferment salicin, mannitol, inulin, or æsculin, and poor production of acid in glucose broth. These organisms belong to Lancefield's Group C and are often referred to as *Str. dysgalactiæ* (Stableforth 1942). Contagion from the hands of the milker plays no obvious part in this type of mastitis. Usually only one quarter of the udder is affected. The condition is, however, often very acute, and may lead to the partial or complete destruction of the quarter involved.

We may also include in this group the sorbitol-positive trehalose-negative sub-group of Lancefield's Group C strains of hæmolytic streptococci (see p. 581).

Group III streptococci are a much less important cause of disease. They are characterized by absence of hæmolysis, production of acid in litmus milk at 10° C., reduction of methylene blue in milk, and fermentation of salicin, mannitol, and inulin. They do not fall into any of Lancefield's groups. They are sometimes referred to as *Str. uberis*.

Streptococcus pyogenes.—This organism is occasionally isolated from cows suffering from mastitis. The udder is probably infected from the nasopharynx of the milker or other human carrier. Its presence in the milk is likely to be followed by outbreaks of sore throat or scarlet fever in persons consuming it in the raw state (see p. 580 and Chapter 93).

MASTITIS DUE TO C. PYOGENES.—This organism is responsible for so-called "summer mastitis." The disease is rather more frequent during the second half of the year. It is far commoner in dry cows than in cows in milk, and usually develops shortly before calving. One or more quarters of the udder are affected. Constitutional symptoms, sometimes accompanied by swelling of the hock joints, are not uncommon. The condition is often chronic, and abscesses in the udder tissue may break through the skin. Microscopical examination of the udder secretion reveals enormous numbers of Gram-positive diphtheroid bacilli, which, when cultivated on coagulated blood serum, give the typical pitted appearance due to liquefaction.

STAPHYLOCOCCAL MASTITIS.—This form usually occurs a few days after calving. One or more quarters of the udder are affected. The disease is sometimes acute, accompanied by gangrene and may prove fatal. More often, however, it is of the chronic catarrhal type (see Minett 1937). The discharge from the affected quarters contains large numbers of hæmolytic staphylococci. Occasionally a chronic granulomatous condition develops; this is usually referred to as actinomycosis but is more properly termed botriomycosis.

Diagnosis of Mastitis.—In its more severe forms mastitis can be detected by clinical means alone, but the chronic streptococcal types of infection usually call for laboratory assistance. Individual quarter samples of milk are preferred for examination, the fore-milk being the most suitable. In well-marked cases of the streptococcal disease flakes in the fore-milk are visible against a dark background; the reaction of the milk is more alkaline than normal; on centrifugation of the milk the cellular sediment is found to be increased and to exceed 1 part per 1,000 by the Breed Smear method the cells usually number more than 5 million per ml.; microscopical examination of the centrifugal deposit reveals the presence of fairly long-chained streptococci; and cultivation of the centrifuged deposit shows the presence of streptococci which, on further examination, are found to belong to one of the mastitis groups. The most delicate test consists in the cultivation of the gravity cream or the centrifuged deposit, preferably in deep blood agar containing aesculin and crystal violet (Edwards 1933). For herd tests, composite milk samples from the udders of each cow may be incubated in the presence of sodium azide and bromcresol purple as a preliminary means of detecting milks containing *Str. agalactiæ* (Edwards 1938).

Prevention and Treatment of Mastitis.—The early observations of Minett and his colleagues led these workers to suggest a modified eradication plan for dealing with chronic streptococcal mastitis. The milk of every cow in the herd is examined culturally, and the affected animals are either sold out, segregated on another part of the farm, or, if neither of these courses is practicable, milked last. Strict attention must, of course, be paid to the general hygiene of milking, and every precaution taken to prevent infection of the clean herd. The rationale of this procedure is based on the assumption that *Str. agalactiæ* is an obligate parasite of the cow's udder. More recent work has thrown doubt on such a belief: the organism has, in fact, been found to survive for several weeks, and even months, outside the animal body (see Watts 1941), so that complete success by the eradication method could hardly be expected. Experience has shown this deduction to be true (see Hucker and Harrison 1937, Bull *et al.* 1940, Watts 1941). Nevertheless it is possible by these means to reduce greatly the incidence of overt disease.

Attempts to control infection by vaccine prophylaxis have not been promising (see Hucker and Hansen 1937). On the other hand, treatment of the affected cows by injections into the udder of bactericidal agents has proved very much more satisfactory. Acriflavine and gramicidin (see Watts 1941, Little *et al.* 1941) have both been used with success; but the best results appear to be obtained with sulphonamides; if these fail, then penicillin can usually be relied upon to effect a cure. Irrigation of the udder, which is often effective in streptococcal and staphylococcal infections (see Swett *et al.* 1944), is, however, time-consuming and entails the loss of several days' milk. For this reason there is an advantage in giving sulphonamide by the mouth. The oral administration of sulphanilamide may be recommended for cows infected with *Str. agalactiæ*, though not all cases respond favourably to this form of treatment (Stableforth *et al.* 1942).

Other Streptococcal Diseases of Domestic Animals

It is convenient to discuss in this section a few examples of streptococcal infection of animals, some of them contagious.

Cunningham (1929) described a disease known as *epizootic lymphadenitis* in guinea-pigs, which appears to be due to a capsulated β-hæmolytic streptococcus. The cervical

Streptococcal mastitis is sometimes responsible for severe outbreaks. We may briefly consider the different types.

STREPTOCOCCAL MASTITIS. The streptococci causing mastitis may be divided into [illegible] according to their action on blood agar into three groups.

Group I streptococci—the *Str. agalactiae* (see Chapter 24)—are responsible for the majority of cases of streptococcal mastitis. The incidence of this disease increases with the age of the animal and is high in cows over 5 years of age. A number of quarters of the udder is attacked. Infection probably occurs [illegible] of the teat canal, and is spread by the hands of the milker. The disease is very chronic, and it is doubtful whether complete recovery occurs.

Group II streptococci give rise usually to acute or subacute mastitis, which is more rapid in onset than the chronic form just described. The distinguishing characteristics of Group II streptococci are absence of haemolysis, reduction of methylene blue, failure to ferment salicin, mannitol, inulin, or æsculin, and poor production of acid in glucose broth. These organisms belong to Lancefield's Group C and are sometimes referred to as *Str. dysgalactiae* (Stableforth 1942). Contagion from milker to milker plays no obvious part in this type of mastitis. Usually only one quarter of the udder is affected. The condition is, however, often very acute and may lead to the partial or complete destruction of the quarter involved.

We may also include in this group the sorbitol-positive trehalose-negative sub-group of Lancefield's Group C strains of haemolytic streptococci (see p. 581).

Group III streptococci are a much less important cause of disease. They are characterized by absence of haemolysis, production of acid in litmus milk at 10° C., reduction of methylene blue in milk, and fermentation of salicin, mannitol, and inulin. They do not fall into any of Lancefield's groups. They are sometimes referred to as *Str. uberis*.

Streptococcus pyogenes.—This organism is occasionally isolated from cows suffering from mastitis. The udder is probably infected from the nasopharynx of the milker or other human carrier. Its presence in the milk is likely to be followed by outbreaks of sore throat or scarlet fever in persons consuming it in the raw state (see p. 580 and Chapter 93).

For this reason there is an advantage in giving sulphonamide by the mouth. The oral administration of sulphanilamide may be recommended for cows infected with *Str. agalactiæ*, though not all cases respond favourably to this form of treatment (Stableforth *et al.* 1942).

Other Streptococcal Diseases of Domestic Animals

It is convenient to discuss in this section a few examples of streptococcal infection of animals, some of them contagious.

Cunningham (1929) described a disease known as *epizootic lymphadenitis* in guinea-pigs, which appears to be due to a capsulated β-hæmolytic streptococcus. The cervical

lymph nodes are mainly affected; they are converted into large, thick-walled, fluctuating abscesses containing grumous, pale yellow, granular pus. The disease is generally chronic, and may be confused with pseudotuberculosis (see Chapter 73). Rae (1936) reports a spontaneous epizootic in guinea-pigs, spreading by contact, also due to a β-hæmolytic capsulated streptococcus. It is characterized by great enlargement of the cervical lymph nodes of a non-suppurative type, and multiple necrotic yellowish areas in the myocardium.

In dogs, infection with Group G streptococci may manifest itself as a febrile adenitis of the submaxillary or cervical lymph nodes, which sometimes suppurate, or by an infection of the genital tract in bitches, resulting in sterility or abortion. The infection may be complicated by a fatal septicæmia (Hare and Fry 1938).

A type of alpha-hæmolytic streptococcus, serologically related to Lancefield's Group C streptococci, was found by Blakemore, Elliott and Hart-Mercer (1941) in suppurative polyarthritic lesions of lambs suffering from *joint-ill*. In some animals the polyarthritis was accompanied by an infective endocarditis. Normal lambs were susceptible, but convalescent lambs and adult sheep were immune to experimental infection with the streptococcus.

Group C streptococci are commonly found in infections of the horse. Bazeley and Battle (1940) described five sub-types of equine Group C streptococci, all of which were associated with respiratory catarrhs, wound infections and suppurative lesions in various parts of the body. Their Type 1 appeared to be the causal organism of *strangles*, a suppurative lesion of the upper respiratory tract, characterized by abscesses in the throat and submaxillary region. Bazeley (1940) was able to immunize mice against infections by this organism, using vaccines of heat-killed capsulated streptococci.

Conjunctivitis.—One of the commonest causes of acute conjunctivitis is the Koch-Weeks bacillus, which seems to be identical with *H. influenzæ* (see Chapter 33). This condition appears to be widespread, occurs in epidemic form, and shows a definite seasonal prevalence in different countries. It is particularly common in Egypt, where the bacillus was first isolated by Koch. Another, less common, cause of conjunctivitis is the pneumococcus. This type of infection, which is more severe than that due to the Koch-Weeks bacillus, is irregular in distribution, is confined chiefly to children, and may occur in localized epidemics. It is more common in Eastern than in Western countries. Subacute, or angular, conjunctivitis is due to the Morax-Axenfeld bacillus (see Chapter 34). Gonococcal conjunctivitis—ophthalmia neonatorum—is described in Chapter 65. (For a general account of the bacteriology of conjunctivitis see Axenfeld 1928.)

Suppurative Lesions in Bones and Joints.—Acute osteomyelitis, occurring independently of a compound fracture, is almost always due to infection with *Staph. aureus*. It occurs mainly in children, in whom it not infrequently develops after a simple blow, or similar trauma. The infection is blood-borne. Acute suppurative periostitis is rare. When it occurs, it is usually a streptococcal infection. A subacute, or chronic, periostitis occasionally occurs as a sequel of typhoid, or paratyphoid fever, and is caused by the bacillus responsible for the primary infection. Such abscesses occur most commonly over the ribs, or the cranium.

A metastatic purulent arthritis may occur as a sequel to infection with any pyogenic bacterium; though the pneumococcus is the organism most frequently isolated in such cases. Other bacteria are rarely isolated from true suppurative arthritis in man, except in those cases which follow wounds entering the joint. In animals other bacteria are often responsible for this condition, as, for instance, *Corynebacterium pyogenes* and *Erysipelothrix rhusiopathiæ*.

Suppurative Lesions of the Alimentary Tract.

Appendicitis.—The bacteriology of acute appendicitis, and of the associated appendix abscesses, is very confused. It is possible that the primary lesion occurs in the wall of the appendix, and that it is due to a blood-borne infection with a streptococcus of the viridans type (see Rosenow 1915). The complex bacterial flora of this part of the intestine ensures a rapid secondary invasion of the damaged tissue with a host of different bacteria, among which *Bact. coli* is prominent; and the bacteriology of the lesion found at operation is correspondingly complex. Veillon and Zuber (1898), using a combination of aerobic and anaerobic methods, examined 22 cases of appendicitis. From 19 cases they isolated anaerobic bacilli associated with rare streptococci and coliform bacilli; from 2 of the cases anaerobic bacilli alone were cultured. Usually 5 or 6 different species were found together, and never less than two. Of the anaerobic bacilli the majority belonged to the Gram-positive non-sporing group, described in Chapter 18; amongst these *Fusiformis fragilis*, *F. ramosus*, *F. fusiformis*, and *F. furcosus* were the commonest. *Cl. welchii* was also found very frequently. More recently Weinberg and his colleagues (1926, 1928) examined 150 cases of acute appendicitis, a great number of which were of the gangrenous type. Of the aerobic bacteria the frequency was *Bact. coli* 128, enterococcus 41, *Proteus* 14, *Staphylococcus* 12, and *Streptococcus* 10; a few other species of organisms were found occasionally. Of the anaerobic bacteria the frequency was *Cl. welchii* 49, Gram-negative rod-shaped organisms 60, cocci and streptococci 40, *F. ramosus* 16, *Cl. fallax* 5, *Cl. septicum* 2, *Cl. histolyticum* 2, and other organisms in smaller numbers. Essentially similar results have been recorded by Schmitz (1930) and Buttiaux and Tiprez (1933). It is clearly impossible on the present evidence to assess the rôle played by each of these organisms in the ætiology of appendicitis, but it would appear not improbable that the organisms responsible for the gangrene and the general toxæmia in severe cases belong mainly to the anaerobic groups. Weinberg and his co-workers (1928) are so impressed with the importance of the anaerobes that they have recommended the use of antitoxic serum prepared against these organisms in the treatment of appendicitis (see Chapter 78).

Cholecystitis.—The frankly suppurative form of cholecystitis appears to be due, in the majority of cases, to infection with *Bact. coli*, sometimes associated with streptococci. Acute cholecystitis may follow infection with *Bact. coli*, with *Salm. typhi*, or with bacilli of the paratyphoid group. The relation between infection of the gall-bladder and the carrier-state in typhoid fever, will be discussed in Chapter 69. It may be noted that infections of the gall-bladder provide an interesting example of the importance of local conditions, of a semi-mechanical nature, in originating or perpetuating bacterial infection. Bacteria, and particularly members of the coli-typhoid group, have frequently been isolated from the interior of gall-stones. It is highly probable that a mild bacterial infection so alters the local conditions in the gall-bladder as to favour the formation of gall-stones, and that the cholesterol and bile salts of which these are composed may be deposited on a central nidus of desquamated cells, or fibrin, containing bacteria. There are also good reasons for believing that the presence of gall-stones greatly increases the liability to bacterial infection; so that we have a vicious circle, each abnormality tending to promote, or perpetuate, the other. The bacteriology of gall-bladder infections is also of interest, in that it provides an example of the selective action of certain body fluids on bacteria, and illus-

trates the necessity for making due allowance for such factors in interpreting bacteriological findings. We have noted elsewhere that some authorities believe that the typhoid bacillus gains access to the gall-bladder *via* the blood vessels of the wall of the viscus, and not by the bile ducts. It has been suggested by many observers that the same is true in the majority of cases of cholecystitis, and that the primary lesion is a focus of infection beneath the epithelial lining. Rosenow (1916) has suggested that streptococci, with a special tendency to localize in the gall-bladder wall, play an important part in the production of cholecystitis in man. Wilkie (1928) has recorded an interesting series of observations, which tend to support this view. In 50 cases of cholecystitis, mainly chronic, he took cultures from the bile, the gall-bladder wall including all coats, the submucosa, and the small lymphatic gland situated near the junction of the cystic duct and the gall-bladder. From the bile, and from the pieces of gall-bladder wall which were contaminated with bile, he isolated streptococci on two occasions, *Bact. coli* three times, and *Cl. welchii* once. From the submucosal cultures, in which special care had been taken to prevent contamination with bile, he isolated streptococci in 21 cases, and *Cl. welchii* once. From the cystic gland he isolated streptococci in 43 cases, *Bact. coli* once, and *Cl. welchii* once. He concludes that cultures taken from the bile give an entirely misleading picture of the essential bacteriology of cholecystitis, owing to the inhibitory action of the bile salts on the streptococcus, which is the cause of the primary infection. These observations clearly suggest that *Bact. coli* may, in many cases, play the part of an important secondary invader, favoured by the selective action of the bile, rather than that of a primary agent.

Peritonitis.—Some cases of peritonitis are primary, for example, certain cases in children due to infection with the pneumococcus; but the great majority of cases are secondary to some primary intra-abdominal lesion, such as appendicitis, perforated gastric or duodenal ulcer, or some type of intestinal obstruction. The species of bacteria concerned in the primary invasion of the peritoneum depends in part on the nature of the primary lesion, in part on the flora of the section of the intestinal tract involved. In intestinal obstruction the bacteria from within the intestine tend to make their way through the intestinal wall, and to produce a mixed infection. In such cases, and in the later stages of any infection of the general peritoneal sac, other than those which are acutely fatal, the bacteriological picture is usually dominated by the colon bacillus.

Fatal post-operative peritonitis is often due to infection with a hæmolytic streptococcus, and a similar infection may occur as part of a septicæmic infection. Pelvic peritonitis, following salpingitis, is usually due to the gonococcus. Other bacteria which may be found in the peritoneal exudate include *Staph. albus*, bacilli of the *Proteus* group, and *Ps. pyocyanea* (see Dudgeon and Sargent 1905). In those cases in which free transit has occurred from the interior of some part of the lower intestine, anaerobes of the *Fusiformis* and *Clostridium* groups may be present. Cazzamali and Miglierina (1933), who examined 81 cases of acute peritonitis, found that aerobic organisms accounted for about two-thirds and anaerobic for about one-third of the total number isolated. In point of time the aerobic organisms preceded the anaerobic. *Bact. coli* seemed to be able to diffuse more rapidly through the peritoneal cavity than any other organism, while streptococci persisted for the longest time. In cases of perforated gastric or duodenal ulcer no organisms could be detected for 6, or even 12 hours, but after this time the peritoneal

cavity was always infected, the commonest organism being a non-hæmolytic streptococcus. From a prognostic point of view, excluding infections with *Str. pyogenes*, the fewer organisms and the fewer species there are present, the more favourable is the outlook (see also Meleney *et al.* 1931).

Suppurative Lesions of the Respiratory Tract.

Suppurative lesions of the accessory sinuses of the nose usually arise by direct extension from the nares or nasopharynx, and the bacteria most frequently responsible are the potentially pathogenic constituents of the nasopharyngeal flora—*Str. pneumoniæ*, *Str. pyogenes*, and *H. influenzæ*. Another organism frequently isolated from cases of suppurative sinusitis is *Staph. aureus*; while acute infection of the nasal sinuses with the meningococcus has been described, and is believed by some observers to play a part in the genesis of cerebrospinal meningitis (see Chapter 64).

Under this heading, we may, for convenience, include otitis media. The great majority of cases in man are caused by *Str. pyogenes*, *Str. pneumoniæ*, or *Staph. aureus* (Fisher 1929); occasionally enterococci are responsible (Rantz and Kirby 1943). Middle-ear disease is very common in rats, particularly in adult animals; the main organisms involved appear to be *Actinobacillus actinoides*, streptococci, and diphtheroids (Nelson and Gowen 1930).

The bacteriology of infections of the lungs is discussed in Chapter 74. Suppurative inflammation of the pleural cavity arises by direct extension from the pulmonary lesion, and is due to the same infecting agent—in most cases of lobar pneumonia to *Str. pneumoniæ*, of secondary broncho-pneumonia to *Str. pneumoniæ*, *Str. pyogenes*, or occasionally to some other organism. The bacterial flora of chronic bronchiectatic cavities in the lung is mixed, pyogenic organisms and throat flora usually predominating. Allison, Gordon and Zinnemann (1943) have produced evidence suggesting that, among respiratory pathogenic bacteria, *H. influenzæ* is most commonly associated with these lesions.

Pneumonia is common in adult rats and appears to be due to very much the same organisms as those responsible for otitis media. A pneumococcal pneumonia occurs in guinea-pigs debilitated by pregnancy or an ill-balanced diet; the infection, which is usually due to Type XIX pneumococci, may also take the form of a respiratory catarrh, or give rise to a uterine lesion (see Petrie 1933). It may be noted that Jowett (1930, 1931) has described a *chronic pyobacillosis of sheep*, met with in the abattoir, which is characterized by multiple small abscesses in the lungs and sometimes other parts of the body. The causative organism is a Gram-negative ovoid bacillus, said to be identical with the *Bact. purifaciens* of Christiansen.

Acute Suppurative Lesions of the Urinary Tract.

Acute suppurative infections of the urinary tract leading to pyelitis, pyelonephritis, and cystitis are caused most frequently by *Bact. coli*. Dudgeon, Wordley, and Bawtree (1921, 1922–23) have drawn attention to the frequency with which hæmolytic types of *Bact. coli* are found in such infections, and have noted that these hæmolytic strains are particularly frequent in males. In a series of 44 *coli* infections in males, 72·7 per cent. were due to the hæmolytic and 27·3 per cent. to the non-hæmolytic type; in 116 female cases, on the other hand, only 31 per cent. were due to the hæmolytic, and 69 per cent. to the non-hæmolytic type. More recently Dudgeon and Pulvertaft (1927) have described a particular type

of acute urinary infection, associated as a rule with acute pyelitis or pyelonephritis, and caused by a hæmolytic, slow-lactose-fermenting type of coliform bacillus. The general symptoms at the onset are so severe that the urinary affection is often masked, and the true nature of the disease is not manifest for 2 or 3 days, when pus is found in the urine. In most cases recovery occurs, and the urine clears up completely, contrasting in this respect with infections due to the typical non-hæmolytic *Bact. coli*, in which chronic bacilluria is the rule.

Bact. aerogenes is said to be frequently present in infections of the genito-urinary tract (Hill *et al.* 1929, Wernig 1939 ; see also p. 2027). Another common invader is *Proteus vulgaris* (Taylor 1928) ; in acute cases this organism can be isolated from the blood stream, and may be present in pure culture in the urine. *Proteus vulgaris*, fæcal streptococci, *Ps. pyocyanea* and staphylococci are not infrequent secondary invaders in infections of the urinary tract. Infection of the urine with the gas-producing *Cl. welchii* may occur in cases of carcinoma of the rectum or bladder, associated with a recto-vesical fistula. Cystitis is a not uncommon complication of gonorrhœa, and is then due to the gonococcus, alone or in association with other organisms. Tuberculous cystitis or pyelonephritis, which is itself associated with pyuria, is frequently complicated during its later stages by a secondary infection with *Bact. coli*, staphylococci, or other organisms.

Infections of the bladder and of the pelvis of the kidney provide another illustration of the importance of local mechanical factors in promoting bacterial infection. Renal or vesical calculi, enlarged prostate, urethral stricture, vesical papilloma or carcinoma, are all conditions which, sooner or later, are associated with an infective cystitis. *Staph. aureus* is the organism most commonly found in urinary calculi, both in the stone itself, and in the adjacent tissues (Hellström 1924, Winsbury-White 1935).

Pyelonephritis is sometimes observed in *cattle* and is characterized by a membranous necrotic inflammation, which attacks principally the papillæ and leads to progressive destruction of the kidney ; there is an accompanying inflammation of the capsule, and often considerable fibrosis of the pelvis of the kidney, the ureter, and the bladder. The ætiology of this condition is still uncertain. By some it is said to be due to a Gram-positive diphtheroid bacillus, *C. pyogenes* ; by others to a mixed infection with *C. pyogenes*, streptococci, coliform bacilli, and other organisms (Glage 1928, Jones and Little 1930).

Infection of Wounds

Bacterial infection is a common sequel to wounding. All wounds, from trivial cuts to the extensive areas of destruction that follow burning, are liable to infection, though in general the larger and deeper the wound and the more damaged and " devitalized " the wounded tissues, the greater is the susceptibility to infection. The risk of infection to a clean operation wound, closed so as to heal by first intention, is relatively small ; and that of an extensive compound fracture, with crushing or laceration of the tissues, is high. Few organisms are introduced into a clean operation wound, and after operation the wound can be adequately protected against subsequent infection. The same is true of the " physiological " wounds in the genital tract of the post-parturient woman ; sepsis does not develop if precautions are taken against the introduction of bacteria during and after labour. The accidental wound, whether inflicted in civil life or in war, differs in that the tissues are usually more damaged, and in the greater likelihood that the wound

will be contaminated by bacteria present in the environment of the wound at the time of infliction. The bacteria include those from the skin and clothes of the wounded person, and those from the soil, dust, dirt and other debris that fall on or are driven by force into the wound. Infection in these wounds is much commoner and has been studied more extensively than has infection of clean wounds. There is, however, no essential distinction between the two kinds, and our conclusions will apply with varying force to infection of all open lesions of the body.

It will be convenient to make an arbitrary distinction between the bacteria we find in a wound within a few hours of infliction, and those we find later. In the fresh wound, bacteria have had little time to multiply and elaborate their toxins, and there is practically no evidence of an inflammatory tissue response. Hence, with few exceptions we can regard the bacteria as contaminants. After a few hours, however, if signs of inflammation or other tissue response appear, we must consider them no longer as contaminating but as infecting bacteria. With this distinction in mind, it remains to determine the relation of the contaminating to the infecting organisms.

Wound Contamination.—If we except wounds grossly soiled with materials which, like road-dust, earth, saliva or fæces, contain large numbers of bacteria, the freshly inflicted wound contains relatively few viable organisms. But, though the numbers are small, a variety of different species is usually present; and few wounds are completely sterile. The frequency with which different bacteria are isolated depends partly on the methods of cultivation employed, and partly on the environment of the wound at the moment of its infliction. In general, micrococci and staphylococci other than *Staph. aureus* are most commonly found. Other frequently isolated species are spore-bearing bacilli (both aerobic and anaerobic), enterococci, α-hæmolytic and non-hæmolytic streptococci, diphtheroids and Gram-negative intestinal bacilli. (See Pulaski, Meleney and Spaeth 1941, Spooner 1941*b*, Hare and Willits 1942, de Waal 1943, Altemeier and Gibbs 1944.) Of the more pathogenic bacteria, *Staph. aureus* is present in up to 20 per cent. of wounds, and *Str. pyogenes* (Lancefield's Group A) in only a small proportion (see Williams and Miles 1945). *Cl. welchii*, though relatively common, behaves in the great majority of wounds as a saprophyte, and dies out fairly rapidly (see Chapter 78). So, in fact, do most of the contaminating species mentioned above, including *Staph. aureus* and *Str. pyogenes*, especially if dead tissue and foreign matter are removed from the wound. The results of repeated cultivation of the flora at intervals after infliction of the wound suggest that only in a small proportion of surgically treated wounds do the initially contaminating pathogenic bacteria persist and give rise to infection.

Wound Infection.—The bacterial flora of the infected wound is both qualitatively and quantitatively different. The organism most commonly found is *Staph. aureus*, which is present in the majority of open infected wounds (see, for example, Levaditi *et al.* 1939, Miles *et al.* 1940, Pulvertaft 1943, Meleney 1943). Next in frequency come *Str. pyogenes*, *Bact. coli*, *Proteus vulgaris*, *Ps. pyocyanea* and enterococci; the precise frequency will vary with the type and age of the wounds studied (see Altemeier 1942). In the large war wounds, as Fleming (1915) showed, the primary stage of infection, which lasts about one week, is due mainly to bacteria of fæcal origin, including spore-bearing bacilli; in the second, intermediate stage, these organisms are gradually replaced by pyogenic cocci; and the third stage is characterized by a suppurating infection with streptococci and staphylococci. But there is no general rule that applies to all the observed varieties, both clinical and bacteriological, of wound infection. Heavy infections with coliform bacilli may occur, particularly in large wounds of the trunk, buttocks and thighs (de Waal 1943); whereas in wounds of the extremities coliform infections are rare (see Williams and Miles 1945). In addition to the common pyogenic organisms and the gas-gangrene or tetanus bacilli noted above, wounds may, for example, become infected with anaerobic

streptococci, diphtheria bacilli, actinomyces, organisms of the *Hæmophilus* group and so forth. Among the anaerobic streptococcal infections we may note a gangrenous myositis, resembling clostridial gas gangrene in many respects, which is apparently due to the combined invasion of wounded muscle by *Str. pyogenes* and anaerobic streptococci (MacLennan 1943*a*, *b*). Wound diphtheria is uncommon, but when it does occur, it may assume epidemic proportions in hospital wards (Bensted 1936).

It must be emphasized that wounds may become infected without any obvious clinical manifestation of disease except perhaps a prolongation of the healing time. Miles (1944), for example, records that 29·0 per cent. of 282 small industrial wounds were latently infected in this way, mainly with *Staph. aureus*. The existence of such wounds is clearly of epidemiological importance, being analogous to the healthy carrier of disease in other infective conditions.

The Sources of Pyogenic Wound Infection.—The three chief bacterial causes of wound sepsis are *Staph. aureus*, *Str. pyogenes* and Gram-negative intestinal bacilli. We have already considered the distribution of *Str. pyogenes* in Chapter 66. We may recall that it is present in the throat of 5–10 per cent. of healthy persons and in the nose of less than 1 per cent.; and that persons with open streptococcal lesions—scarlet fever, tonsillitis, and streptococcal skin diseases—contribute large numbers of cocci to their surroundings. Streptococcal wounds are also prolific sources of this organism. Under ordinary conditions, however, *Str. pyogenes* is found infrequently and in small numbers on the skin and clothes, even of carriers (see Hare 1941)—a fact in accord with the very low incidence of *Str. pyogenes* in freshly inflicted wounds. Coliform bacilli are present on the skin near the anal region, and it is reasonable to suppose that large trunk and buttock wounds are often infected by fæcal organisms on the neighbouring skin. In *Staph. aureus* we have a potentially pathogenic organism existing normally in close association with man, at least in the temperate regions where the carriage of this organism has been investigated. The distribution of *Staph. aureus* in man is considered in detail in Chapter 90. It is sufficient to note here that the observed carrier rates for adults are about 50 per cent. for the anterior nares, and 5–20 per cent. for the skin of the hands (see Gillespie *et al.* 1939, Miles *et al.* 1944). A smaller percentage of persons carry it on the skin in various other parts of the body (Martin 1942, R. E. O. Williams, personal communication). Skin carriers are usually nasal carriers; and, in view of the persistence and profuseness of nasal carriage, it would appear that the nose is the primary source of the external *Staph. aureus* of the body, and that the skin is secondarily contaminated from the nose.

Miles and his colleagues (1944) have observed that wound contamination by *Staph. aureus* is commoner among skin carriers than among those whose skins are free from the coccus; and, in the majority of cases tested, the skin staphylococcus was of the same bacteriophage type as the wound staphylococcus. The fact that nasal and skin strains in one person usually belong to the same serological or phage type (Gillespie *et al.* 1939, Fisk and Mordvin 1944, Miles *et al.* 1944) strongly suggests that both contamination and infection of wounds by the patient's own staphylococci are common.

The incidence of infection by these organisms in older wounds is far higher than we should expect from the initial contamination rates. Moreover, in the severer wounds, the infection rates with various organisms increase with the age of the wound. Thus, in the war of 1914–18, it was observed that hæmolytic streptococci were present in about 15 per cent. of pre-operative wounds, and in as many as 34·6 per cent. (Stokes and Tytler 1918–19) and 90·0 per cent. (Fleming and Porteous 1919) of wounds after a week or more of post-operative treatment. Similar observations with respect to *Str. pyogenes*, *Staph. aureus*, coliform bacilli, and other organisms, were made in the second world war (see Memorandum 1941, Spooner 1941*a*); and it appears that in a large number of cases, the infections are added after the infliction of the wound. For the most part the evidence of added infection is circumstantial, for there is no direct means of excluding the possibility that the late-appearing infections arise from bacteria that have lain dormant in the wound since its infliction, but which eluded bacteriological detection by reason of the small

number of organisms present. With *Str. pyogenes*, however, the evidence is more direct. As in epidemiological surveys of other streptococcal diseases (Chapter 66), the identification of the various Griffith types of *Str. pyogenes* has made it possible to prove that infection is often due to streptococci added in hospital. There is, then, good reason to believe that in a large number of instances where the precise infecting organism cannot be traced to its source, late-appearing infection is, in fact, due to added infection (see Miles 1944). Not only may a clean wound become infected, but one type of infection may be superimposed on, and eventually replace another. Thus the successive predominating organisms in a wound may, for example, be micrococci, *Staph. aureus*, *Str. pyogenes*, *Ps. pyocyanea* and *Proteus vulgaris*, and finally, immediately before healing, *Staph. albus* and diphtheroids.

The establishment of this point of view is important, for it clearly indicates that antibacterial measures at the time of wounding, the removal from the wound of foreign matter and of devitalized tissues, and the application of cleansing and antibacterial agents, are insufficient safeguards against wound infection. The wound must be protected against the risks of infection until it is fully healed.

The risks are greatest in casualty stations, hospitals and other institutions. They are relatively low in civilian surgical practice, for there are few reservoirs of infection, and most clean operation wounds offer too small a surface for the successful implantation of organisms; but even here cross-infection of the larger, chronic, open lesions like tuberculous sinuses, and abscess cavities after surgical interference, may occur. War and accident wounds are more susceptible to infection, and in war-time the large numbers of infected wounds in hospital wards ensure reservoirs of infection far larger than those of the normal nose, throat and skin carriers of pyogenic cocci. Consequently, added infection of wounds is numerically a greater problem in war. Such infections appear to be transmitted mainly by contact or droplets. *Str. pyogenes*, *Staph. aureus* and coliform bacteria are often found in the air of surgical wards, but their rate of sedimentation is slow and few are likely to fall on to a small wound during its exposure for dressing or inspection; consequently, air-borne infection is of minor importance compared with contact infection. Burns, and other extensive wounds that are exposed for long periods during treatment, appear to be far more susceptible to air-borne infection (Cruickshank 1935, Colebrook and Francis 1941). Precautionary measures comprise aseptic routines carefully devised to meet the known risks of added infection, including air-borne infection in appropriate cases (Memorandum 1941), and the local application of antiseptic or chemotherapeutic substances (see below).

Treatment of Pyogenic Infections

Surgical.—Although the discussion of surgical methods of treatment takes us beyond our proper ground, it is permissible to point out that general bacteriological principles indicate the paramount importance of judicious surgical interference in those acute suppurative infections which are accessible to such measures. The removal, or adequate drainage, of a localized focus of infection will usually enable the defence mechanisms of the body to deal satisfactorily with the remaining bacteria. We have emphasized above the importance of mechanical factors in many cases of acute or chronic pyogenic infections; and the rectification of these abnormalities by surgical means frequently results in a bacteriological cure. It may be noted that other factors, in addition to the removal of living bacteria, are involved in the successful drainage or removal of an infected focus. Reference to the discussion on "aggressins" in Chapter 48 will indicate that the antigenic constituents liberated in such a focus may play a significant part in extending the area of infection, or in favouring its local persistence.

Chemotherapy.—In recent years, a large variety of antibacterial agents has become available for treatment of pyogenic infections. Those with a high thera-

peutic index like the sulphonamides or penicillin may be used for both systemic and local treatment, while active but more toxic substances, like tyrothricin or the acridine compounds are fit only for local application—usually to open lesions (see Chapter 6).

It is beyond the scope of this chapter to discuss the chemotherapy of pyogenic infections in any detail. The sulphonamides have been extensively used, and have proved to be effective in the treatment of streptococcal infections. Staphylococcal infections also respond, particularly to compounds like sulphadiazine and sulphathiazole. Streptococcal septicæmia appears to be more readily influenced than staphylococcal septicæmia by the sulphonamides. These drugs are less effective against infections by Gram-negative bacilli, though their clinical effect is by no means negligible, especially in infections of the urinary tract (see Spink 1942). Penicillin is particularly effective in staphylococcal and streptococcal infections (see, for example, Christie *et al.* 1944, Dawson and Hobby 1944, Herrell 1944, Bloomfield *et al.* 1944).

Local therapy of abscesses, skin lesions, infected wounds, and so forth is practicable, and may be necessary when, for various reasons, it is impossible to maintain a blood concentration of the drug sufficient to ensure a therapeutic concentration in the infected organ. The efficacy of local sulphonamides upon susceptible bacteria depends in part upon their solubility, their activity at the pH of the infected lesion, and the extent to which they are antagonized by substances present in exudates and pus (see Chapter 6). Their toxicity for tissues is low. Penicillin preparations are almost entirely non-toxic, and are not conspicuously antagonized by exudates and pus. (For references see Memorandum 1944). Among other substances that appear to be of value in the treatment of open septic infections we may note tyrothricin (see Herrell and Heilman 1941, Rammelkamp 1942); propamidine (Thrower and Valentine 1943, Clark *et al.* 1943), and acridine compounds (Mitchell and Buttle 1942, Browning 1943).

It should be noted that in the chemotherapy of mixed infections, the relatively insusceptible organisms like *Bact. coli*, *Proteus vulgaris* and *Ps. pyocyanea*, which remain in the lesion after the suppression of the pyogenic cocci, may cause serious and sometimes fatal infection.

Jensen and others (1939) reported that the introduction of sulphonamide into compound fracture wounds protected against subsequent infection; and both local and systemic sulphonamides have been used prophylactically in wounds and in the peritoneal cavity at operation (see Spink 1942). It is difficult to assess their value in preventing the infection of war wounds, where there are so many factors, including concomitant methods of treatment, to take into account; but there is a general consensus of opinion that they are of value (but see Meleney 1943).

The induction of drug-fastness in bacteria subjected to less than bacteriostatic concentrations of antibacterial agents is a possibility to be borne in mind in the treatment of open lesions. There are on record a number of ward epidemics of streptococcal infection of burns and wounds, caused by a drug-fast strain of *Str. pyogenes* (see Colebrook *et al.* 1944); but, though there was in each case ample opportunity for the therapeutic induction of drug-fastness in the epidemic strain, no proof that it had become drug-fast under these conditions was in fact forthcoming.

Serotherapy.—The probability that staphylococci exert their deleterious action on the tissues by means of toxins holds out some hope of the value of serum treatment. There is evidence (Chapter 46) that resistance in the experimental animal to the bacterial infection is associated with a high antitoxin content of the blood;

this presumably acts by protecting the cells of the host against the necrotic effects of the α-toxin elaborated by the invading *Staph. aureus* (see Rigdon 1936). Antitoxic serum, capable of neutralizing the hæmolytic, skin-necrosing, lethal, and leucocidal properties of the toxin, can be prepared by inoculation of horses with formolized, and later with pure, toxin. Its α-antitoxin content can be titrated in one or other of the following ways.

(1) By testing mixtures of toxin and antitoxin for their hæmolytic activity towards rabbit red blood corpuscles. In practice the test dose of toxin (LH) is determined which, when mixed with one provisional unit of antitoxin, causes partial hæmolysis; this test dose is then used for titrating the unknown antitoxin; (2) by inoculating toxin-antitoxin mixtures in 0·2 ml. quantities intracutaneously into guinea-pigs of 300–400 grams. The test dose $\frac{Lr}{10}$ is the quantity of toxin which, when mixed with 0·1 provisional unit of antitoxin, causes a small but characteristic necrotic lesion in 24–48 hours; (3) by inoculating toxin-antitoxin mixtures in 0·5 ml. quantities intravenously into mice. The test dose employed is that quantity of toxin which, when mixed with one provisional unit of antitoxin, causes death of half the mice within three days; (4) by inoculating toxin-antitoxin mixtures in 0·5 ml. quantities intraperitoneally into mice. The procedure is similar to method (3). The international unit is now defined as the specific antitoxic activity contained in 0·5 mgm. of the dry standard preparation preserved at the National Institute for Medical Research, London. (See Hartley and Smith 1935, Smith 1938). Antisera also contain variable amounts of antibody to the leucocidin described by Panton and Valentine (1932), who ascribe the beneficial effects of staphylococcus antitoxin in part to its anti-leucocidin content (see also Valentine 1936). As mentioned on p. 616, this leucocidin is to be distinguished from the Neisser-Wechsberg leucocidin, which is reported to be similar to the α-toxin.

Though staphylococcal antitoxin has been generally available for some years, information about its value is scanty. It appears to be most effective in the treatment of severe local or generalized infections accompanied or likely to be followed by septicæmia, though only in a proportion of such cases is there a favourable response. The intravenous injection of large doses, in some instances totalling 600,000 units, is recommended, together with drainage of accessible lesions, whether in the soft tissues or bones (Dolman 1934*a*, *b*, Joyner and Smith 1936, Baker and Shands 1939). Goldberg and Bloomenthal (1941) report a synergic action of antitoxin and sulphonamides in the treatment of staphylococcal septicæmia.

Julianelle (1939, 1942) reports a beneficial effect in severe staphylococcal infections of an antiserum prepared against Type A staphylococci (see Chapter 25), most marked in cases of osteomyelitis accompanied by septicæmia.

Antiscarlatinal (antitoxic) and the ordinary type of antistreptococcal serum, which have already been described in relation to the treatment of scarlet fever and puerperal sepsis (Chapter 66), have on the whole given disappointing results in cases of septicæmia.

Vaccination.—Examination of the blood serum of man and animals has shown the presence in small amounts of natural antitoxin to staphylococci (see Bryce and Burnet 1932, Parish, O'Meara, and Clark 1934, Murray 1935, Nélis and Poncelet 1935, Gernez and Pannequin 1937, Weiss 1939). In normal human adults and new-born babies the antitoxin titre expressed in terms of international units is generally about 0·25–0·75 units per ml. In patients suffering from superficial staphylococcal infections, such as acne, blepharitis, furunculosis, and sycosis, the average titre is very slightly higher or practically unaltered. In cases of

carbuncles the titre is often slightly raised, while in cases of chronic osteomyelitis it is generally high, though not always so (see Blair and Hallman 1935–36), and may reach 15 units or more per ml. Experimentally and clinically it has been found that treatment of animals and patients suffering from chronic staphylococcal infections with formolized toxin—toxoid—but not with staphylococcal vaccines, is often followed by a rise in the antitoxin titre and considerable improvement in the local condition; though there seems to be no definite relationship between the absolute titre attained and the retrogression of the infection. The preparation of the toxoid requires care, and strict precautions must be taken to ensure its innocuity and its antigenic potency (Dolman and Kitching 1935, 1936, Smith 1936, 1937, Farrell 1941). The dosage recommended by different workers varies somewhat. Dolman (1933, 1935) starts with a dose of 0·05 ml., increases by 0·05 ml. weekly, till at the eighth injection 0·5 ml. is given. If a second course of injections is needed, it is probably wise to rest the patient for a month or two. There seems to be fairly general agreement now that toxoid is of considerably more value than vaccines of whole staphylococci. Furunculosis and staphylococcal skin lesions appear to be particularly benefited by toxoid treatment. The results have been disappointing in chronic osteomyelitis (Blair and Hallman 1936, Buchman 1937). In cases of acne, staphylococcal toxoid may well be combined with a vaccine of *C. acnes*. (For reports on this method of treatment see Dolman 1933, 1935, Dolman and Kitching 1935, Connor and McKie 1934, Parish, O'Meara, and Clark 1934, Murray 1935, Whitby 1936, Ramon *et al.* 1936, Mercier 1937.)

Vaccines of *Bact. coli* and of *Proteus vulgaris* are sometimes of use in urinary infections. For further discussion of the value of vaccine treatment the reader is referred to the monograph by Dudgeon (1927.)

CHAPTER 68

THE BACTERIOLOGY OF RHEUMATIC INFECTIONS AND OF ENDOCARDITIS

THE attempts which have been made to solve the problem of the ætiology of acute and chronic rheumatism are legion, and the literature is correspondingly extensive. An adequate review is impossible, and would indeed serve no useful purpose; for the whole subject is at the moment too confused and obscure to allow of any systematic presentation. It may be said that, while most of the earlier observations that yielded positive results tended to inculpate one or another type of streptococcus, the present position of this problem is that interest is focussed on the relation of hæmolytic streptococci to acute rheumatic infection. The earlier studies have, for the moment at least, mainly a historical interest, and may therefore be very briefly summarized.

Westphal, Wassermann and Malkoff (1899) isolated a streptococcus from the blood of a patient suffering from rheumatic endocarditis associated with chorea. In the following year Poynton and Paine (1900, 1913) published the first of their series of papers, in which, on the basis of extensive bacteriological studies in man and numerous experiments on the rabbit, they reached the conclusion that acute rheumatism is the result of infection with a particular variety of streptococcus, or with a closely allied group of streptococcal strains. Since the appearance of their reports, the bacteriologist has been mainly concerned with repeated attempts to determine the real nature of the association between certain types of streptococci and this particular disease. The observations of Poynton and Paine, with regard to the isolation of streptococci from the blood, exudates, or tissues of patients with acute rheumatism have been repeatedly confirmed (Beaton and Walker 1903, Walker and Ryffel 1903, Loeb 1908, Camisa 1910, Beattie and Yates 1912, Rosenow 1914, Lyall 1914, Swift and Kinsella 1917, Quigly 1918, Clawson 1925, Birkhaug 1927, Small 1927, Zinsser and Yu 1928, Kreidler 1928). The distribution of these streptococci in the body is not, however, such as one would expect on the assumption that the rheumatic manifestations are the result of a bacteræmic infection, associated with, or followed by, a localized proliferation in particularly susceptible tissues. In very few instances have the streptococci been cultivated from the joint fluid in acute rheumatic arthritis. Isolation from the blood during life has been successful in a somewhat larger proportion of cases; but a considerable number of the strains described by various authors have been cultivated at autopsy, from the blood, from the pericardial fluid, or sometimes from the spleen. Moreover, the presence of streptococci in the blood, exudates or internal tissues is by no means a constant feature of acute rheumatic infection. In a large proportion of cases cultures obtained during life remain uniformly sterile, and careful bacteriological examinations carried out at autopsy on patients who have died from an acute attack may give entirely negative results (Bulloch 1912). The report by Cecil, Nicholls and Stainsby (1929*a*, *b*) that streptococci could be isolated from the blood of a high proportion of rheumatic patients by the use of a special technique gave a fresh impetus to

work along these lines; but there has been an almost entire failure to confirm their results (see Nye and Seegal 1929, Nye and Waxelbaum 1930, Margolis and Dorsey 1930, Cooley 1932, Dawson, Olmstead and Boots 1932*a*, Lichtman and Gross 1932, Steinfeld 1932).

To summarize: it is seldom possible to cultivate any bacteria from the local lesions during life; blood cultures remain sterile in a large proportion of cases during the febrile stage of the disease; but, in either case, when any bacterium has been isolated, it has almost invariably been a streptococcus; cultures obtained at autopsy have, as would be expected, given growth in a higher proportion of cases, though by no means in all, and here again a streptococcus has been the predominating organism, either in pure culture or in association with those bacteria which occur as common, non-specific contaminants of cultures taken under these conditions.

With regard to the particular type of streptococcus concerned, the great majority of the strains isolated have been definitely described as non-hæmolytic, that is, as not giving rise to true hæmolysis. In many cases, probably in the majority, the organism has been identified as *Str. viridans* by the green coloration given on blood agar; in others, and particularly in some recent reports, the strains described are recorded as being without action on red blood corpuscles.

From the experiments of Poynton and Paine onwards, the study of the lesions produced in rabbits by the intravenous inoculation of streptococci has played a large part in the bacteriological attack on the problem of rheumatic infection. The results of these extensive series of observations may be very shortly summarized. Many of those lesions which are characteristic of rheumatic infection in man have been reproduced in the rabbit as the result of such inoculations. The experimental lesions include endocarditis, non-suppurative myocarditis, and arthritis of all degrees of severity, sometimes associated with extensive, secondary bony changes (Poynton and Paine 1900, 1913, Cole 1904, Wächter 1908, Bracht and Wächter 1909, Coombs *et al.* 1912, Jackson 1912, Rosenow 1914, Topley and Weir 1921, Birkhaug 1927, Small 1927, Gross *et al.* 1929, Clawson 1930, Moon and Stewart 1931). But although the analogy between experimental rheumatism in the rabbit and the natural infection in man is very close, it is not exact. This applies particularly to the myocardial lesions. Aschoff (1904) described in detail characteristic nodular collections of cells in rheumatic myocarditis, and his observations have been fully confirmed by later workers (Geipel 1905, 1909, Fraenkel 1912). In spite of a certain resemblance between some of the myocardial lesions in rabbits and the typical Aschoff nodule (Coombs *et al.* 1912, Jackson 1912), it is very doubtful whether the rabbit lesions can be regarded as pathognomonic (Wächter 1908, Bracht and Wächter 1909, Topley and Weir 1921, Gross *et al.* 1929).

However closely experimental streptococcal infection in the rabbit simulates acute rheumatism in man, it is quite certain that the ability to produce these lesions on intravenous inoculation cannot be regarded as evidence that a particular variety of streptococcus is ætiologically related to the human disease; for many of the streptococcal strains which have produced the most characteristic lesions in the rabbit have been derived from sources quite unconnected with rheumatic infection, and some of them have been actively hæmolytic (Cole 1904, Jackson 1912, Topley and Weir 1921). It is clear that experimental rheumatism in the rabbit is a characteristic reaction of that animal species to the intravenous inoculation of a variety of different streptococci.

Before leaving the problem of the possible relation of these heterogeneous strains of streptococci to rheumatic diseases it should be noted that many observers have suggested the possibility that some forms of rheumatism, at least, are allergic manifestations. This view has, for instance, been developed by Zinsser and Yu (1928) and it receives some support from the relative frequency of allergic skin

reactions to killed cultures of streptococci of various types (see, for instance, Swift, Wilson and Todd 1929).

Hypersensitiveness to the antigens of various streptococci is also common in non-rheumatic subjects (Derick and Fulton 1931), and on this basis it is difficult to relate the allergic state to rheumatic fever. Other observers (see Green 1942*d*) have found that rheumatic subjects are more frequently sensitive to extracts of streptococci and particularly of *Str. pyogenes* than non-rheumatic subjects are. Thus Gibson, Thomson and Stewart (1933) recorded a higher proportion of skin reactions to extracts of hæmolytic streptococci among 140 rheumatic cases than among 145 controls, whereas there was no significant difference between the skin reactions of these groups to extracts of non-hæmolytic streptococci. On the other hand the Dick reaction was positive in only 16 per cent. of the rheumatic cases as compared with 28 per cent. of the controls. The test extracts contained protein material, but the nature of the responsible antigen is not known. The greatest number of positive reactions was obtained in tests with extracts of autogenous streptococci, which suggests some type-specificity; but mixed extracts from several *Str. pyogenes* strains also gave a large number of positive reactions (Green 1938*a*); and the reactivity of extracts from other streptococcal species indicates the possibility of hypersensitiveness to an antigen common to them all.

It will be recalled that serum sickness in man is often associated with minor rheumatic manifestations.

Much of the confusion in regard to this problem is without doubt due to the difficulty of defining, or recognizing, rheumatism as a clinical syndrome, or series of syndromes. We have, in the previous discussion, been mainly concerned with acute rheumatic fever, where the clinical diagnosis is not in doubt, and it is to the ætiology of this condition that the following sections refer.

The Rôle of Hæmolytic Streptococci in Acute Rheumatism.—The possibility that acute rheumatism is one of the manifestations of infection with hæmolytic streptococci was raised in a definite and categorical form by the studies of Coburn (Coburn 1931, 1936, Coburn and Pauli 1932*a*, *b*, *c*, 1935*a*, *b*, *c*, *d*, *e*, *f*, *g*).

The starting-point of these studies was the observation of a close epidemiological relationship, in place and time, between hæmolytic streptococcal infection of the throat and the incidence of acute rheumatic infection. Coburn (1936) identifies three phases in the pathogenesis of the disease; a phase of acute infection of the upper respiratory tract, a second phase in which there is complete absence of signs and symptoms, and a third phase of the rheumatic manifestation proper. It was also found that, in individual cases, a relapse was frequently associated with the reappearance of hæmolytic streptococci in the throat in large numbers. In instances in which this sequence was particularly studied, it was found that acute rheumatic symptoms tended to develop 1 to 5 weeks after the original appearance of hæmolytic streptococci in the throat.

These observations have been amply confirmed by other workers. Thus Collis (1931) notes that an outbreak of tonsillitis in a ward occupied by children suffering from rheumatic heart disease led to a relapse in 9 of 11 children who developed this throat infection and from whose throats a hæmolytic streptococcus was isolated; and Glover and Griffith (1931) describe outbreaks of tonsillitis in schools due to hæmolytic streptococcal infection in which a proportion of the infected boys developed all the symptoms of acute rheumatic fever (see also Schlesinger 1930, Sheldon 1931, Thomson 1934, Green 1942*a*, *b*, *c*). The association between tonsillitis and acute rheumatism is, as Glover and Griffith emphasize, quite an old observation

in its purely clinical aspect, and Newsholme in 1895 called attention to the similarity in epidemiological behaviour between rheumatism, erysipelas, puerperal fever and scarlet fever. As in the case of scarlet fever, the effect of recent studies has been to add precision to this observation by establishing the fact that the true relationship is between acute rheumatism and infection with hæmolytic streptococci, which have proved to be *Str. pyogenes* of Lancefield's Group A (see Pauli and Coburn 1937).

Thus Green (1938*b*) records that of 200 rheumatic subjects admitted to hospital, 50·5 per cent. carried Group A streptococci in the throat, irrespective of any signs of throat infection; the rate in 200 non-rheumatic patients was only 12·5 per cent., although the incidence of a recent history of throat infections in both was approximately the same. An even closer association of the disease with *Str. pyogenes* was demonstrated by Green (1939), who cultivated it from the valvular lesions, but not from the blood, in 8 of 9 fatal cases of rheumatic fever; in the cadavers of 22 non-rheumatic subjects, *Str. pyogenes* was found on the valves only twice, and in these two cases blood cultures were also positive. Collis (1939) examined only rheumatic cases, and found hæmolytic streptococci in 14 of 15 tonsils, 13 of 27 cervical or mediastinal lymph nodes, and 22 of 42 heart valves cultured (see also Thomson and Innes 1940). In the Canadian army about 4 per cent. of persons suffering from streptococcal infection of the respiratory tract are said to have developed acute rheumatism. Of throat cultures taken from 46 patients, 14 yielded no streptococci, 2 yielded *Str. viridans*, and 30 yielded hæmolytic streptococci, all of which, with one possible exception, belonged to Group A (Feasby 1944).

The significance of the epidemiological findings is greatly increased by serological evidence of infection by *Str. pyogenes*. Todd (1932) showed that the acute rheumatic process is almost constantly associated with a wide fluctuation in the titre of antibody to the O streptolysin in the blood of the patient. This fluctuation is of a rather peculiar kind, in that the rise in titre occurs during the acute rheumatic attack, and particularly during a relapse, while quiescent or recovered cases tend to show titres that are not greatly above the normal. These observations have been confirmed by Coburn and Pauli (1932*c*, 1935*a*, *c*, *f*).

Later observations showed that the streptolysin O titre rose in scarlet fever and streptococcal pharyngitis. The response in these two diseases is at a maximum two to three weeks after their onset; that in rheumatic fever occurs rather later—4 weeks or more after the onset (Coburn 1936, Coburn and Pauli 1939*b*, Todd, Coburn and Hill 1939). Green (1941) gives 79 units per ml. as the average titre in healthy subjects, 263 in pharyngitis, 300 in scarlet fever, and 210 in inactive, and 444 in active rheumatic fever.

There is other evidence of a serological response to the antigens of *Str. pyogenes*. Agglutinating and complement-fixing antibodies for hæmolytic streptococci (Coburn and Pauli 1932*c*), antifibrinolysin (Stuart-Harris 1935, Lichty 1941, Mote and Jones 1941), and precipitins for group and type specific antigens of Group A streptococci (Swift and Hodge 1936, Coburn and Pauli 1939*b*, Mote and Jones 1941) resemble anti-streptolysin O in occurring later in rheumatic fever than in other streptococcal infections.

The antibody to the streptolysin S (see Chapter 24) is an exception to this generalization, for though raised in patients with streptococcal infection and rheumatic fever, in the rheumatic subject it is depressed in the acute stage, though not to normal levels (Todd, Coburn and Hill 1939). It should be noted that relatively high antibody levels may be found in apparently healthy persons with no history of recent infection by streptococci (Solomon 1943): and that the correlation between antibody response and rheumatic fever is not complete; in a small number of cases typical rheumatic attacks may take place without change in antibody titre.

There are many indications that an important genetic factor is concerned, and that certain individuals have a special tendency to respond to infection with hæmolytic streptococci in this particular way (see Green 1942*c*, Wilson, Schweitzer and Lubschez 1943).

In summary, the evidence that hæmolytic streptococci play a significant part in the pathogenesis of acute rheumatic infections is strong, but it is by no means complete. An initial streptococcal pharyngitis is common, but may be absent in a few cases. In recent years, hæmolytic streptococci have been found in rheumatic lesions, but not in all cases; these results are in marked contrast to those of earlier workers. There is further support for the rôle of hæmolytic streptococci in the fact that the prophylactic administration of sulphonamides to rheumatic subjects has, in a number of controlled tests, apparently reduced the incidence both of streptococcal infections of the upper respiratory tract, and of the rheumatic recurrences that usually follow them (Coburn and Moore 1939, 1941, Thomas 1942, Hansen, Platou and Dwan 1942, Kuttner and Reyersbach 1943, Feldt 1944). The serological response to various antigens of hæmolytic streptococci is also suggestive, but here again it is not an invariable concomitant of rheumatic fever. From the lack of an antitoxin response in the rheumatic subject, and from the failure of immunization with *Str. pyogenes* toxin to prevent the development of acute rheumatism (see Coburn and Pauli 1935*a*), we may conclude that the erythrogenic toxin plays little part in the disease process. The probable participation of other soluble antigens is suggested by the reports of a reduction of rheumatic recurrences in children immunized by repeated doses of filtrates prepared from cultures of hæmolytic streptococci (see Wasson and Brown 1942).

Even though we accept the broad indications of the streptococcal rôle in acute rheumatism it is clear that, compared with typical infections like pharyngitis or scarlet fever, the rheumatic response to the streptococcus is curiously delayed. The cause of this abnormality does not appear to lie in the organisms themselves, for they do not demonstrably differ from strains associated with other types of infection. Poverty, bad housing, urbanization, dietary deficiences and hereditary tendencies have all been implicated as predisposing factors (see, for example, Glover 1939, 1943, Morris and Titmuss 1942), but are not easily interpreted in terms of a peculiar reactivity to *Str. pyogenes*. As we have seen in Chapter 54, there is little basis for implicating vitamin C deficiency as a major factor (see also Keith and Hickmans 1938).

We may justifiably invoke allergy to explain some features of the disease; but the question as to why a proportion of the persons infected with hæmolytic streptococci should react in this peculiar manner remains unanswered. Coburn (1940) suggests that the delayed reaction to the initial streptococcal infection is due to an inadequate response of the normal defence mechanisms, which permits the establishment of streptococcal foci in the tissues. The liberation of antigen from these foci results at first in allergic sensitization, and, at a later stage, in a concurrent stimulation of the antibody-forming apparatus and in acute allergic inflammation in other sensitized tissues. The observation of Coburn and Pauli (1939*a*) that, in the quiescent stage after the initial pharyngitis prior to the onset of the rheumatic attack, a substance ("precipitinogen") appears in the blood, which is specifically precipitated by sera taken from the same patient or from other patients in the later acute rheumatic stage, suggests the replacement of a circulating antigen by an antibody specific for it, and to this extent at least offers additional support

for Coburn's view. The "precipitinogen," however, has not yet been identified with any known streptococcal antigen.

The Virus Hypothesis.—Alternatively, we may postulate another infecting agent as responsible, either in conjunction with hæmolytic streptococci, or independently of them.

Schlesinger, Signy and Amies (1935) found that the deposits obtained by high-speed centrifugation of specimens of pericardial fluid from cases of acute rheumatism contained bodies which, in their size and general morphology, closely resembled virus particles. Relatively pure suspensions of these particles in formol saline were agglutinated by sera from patients suffering from, and successfully resisting, an acute rheumatic infection, while they were not agglutinated by normal sera, or by sera obtained from patients suffering from non-rheumatic infections. The authors did not dispute the importance of hæmolytic streptococcal infections in relation to acute rheumatism; but concluded that such infection in some way lowered resistance to invasion with the virus, or reactivated it if it was already present (see also Schlesinger, Signy and Payne 1935).

Subsequent workers were unable to confirm the virus-like nature of these bodies or the specificity of their association with acute rheumatism. The bodies were present, but not consistently, in the cerebrospinal fluid of patients with chorea, and the joint fluids in rheumatoid arthritis (Eagles *et al.* 1937).

The formation of agglutinins for these bodies, moreover, was found to be associated with arthritis, whether rheumatic, rheumatoid, gonococcal or pneumococcal and not with the specific rheumatic state (Eagles and Bradley 1939). Attempts to reproduce rheumatism experimentally by inoculating fresh rheumatic exudates containing the bodies into the joints or the pericardial cavity of monkeys, proved fruitless (Eagles *et al.* 1938).

Rheumatoid Arthritis.—It may be noted that there is both epidemiological and serological evidence that rheumatoid arthritis is associated with hæmolytic streptococcal infection; high agglutinin, precipitin and antistreptolysin titres have been reported in patients suffering from this disease (Dawson, Olmstead and Boots 1932*b*, Dawson, Olmstead and Jost 1934, Dawson and Tyson 1936, Neil and Hartung 1937; see also Goldie 1938).

Bacterial Endocarditis

Although this disease bears no immediate or necessary relationship to acute rheumatism, it is convenient to consider it in this chapter, if only because the isolation of non-hæmolytic streptococci from the blood stream in the more chronic cases of this kind has perhaps done something to confuse the issue in regard to the causation of simple rheumatic endocarditis.

The bacteria most commonly found in large proliferating and ulcerating lesions of the heart valves are the various pyogenic cocci: hæmolytic streptococci, streptococci of the *Str. viridans* and *Str. fæcalis* types; pneumococci, gonococci and meningococci; *Staph. aureus*, *Staph. albus* and micrococci of various kinds. Of other bacteria, bacilli of the *Hæmophilus* group occur with the greatest frequency (see Perry 1936), though endocardial infections with members of the *Bacterium* and *Bacillus* groups, with salmonellæ, brucellæ, corynebacteria, clostridia (see More 1943) and so forth, have occasionally been reported.

In a number of instances, the endocarditis is apparently secondary to infection elsewhere in the body, usually by the more pathogenic organisms like *Staph. aureus*, *Str. pyogenes* or the pneumococcus. In others, the infection of the heart valves

is apparently primary, and usually runs a less acute, though no less fatal course than that in the first group.

Subacute Bacterial Endocarditis.—There can be no question that this fatal disease is due in the great majority of cases to the infection of a previously damaged, or congenitally abnormal, valve with streptococci, either of the viridans or of the enterococcus type (see Moran 1938, Swain 1940, Solowey, 1942), though other organisms, including influenza bacilli and *H. para-influenzæ*, may occasionally be concerned (see, for instance, Horder 1908–9, Schottmüller 1910, Kreidler 1926, Stuart-Harris *et al.* 1935, Miles and Gray 1938, Khairat 1940).

Our knowledge of the pathogenesis of this condition was greatly advanced by the important studies of Lewis and Grant (1923), Grant (1924), and Grant, Wood and Jones (1928) on the pathological side, and by Okell and Elliott (1935) in regard to the probable source and mechanism of infection.

Lewis and Grant (1923) found that 26 per cent. of an unselected series of cases of subacute bacterial endocarditis had a congenitally bicuspid aortic valve; and they calculate, on the basis of their experience, that of these persons with congenitally bicuspid aortic valves who reach adult life, some 23 per cent. die of subacute endocarditis. Grant (1924) and Grant, Wood and Jones (1928) described the lesions of this disease in considerable detail, and gave reasons for believing that they are usually produced by direct infection of the endocardium from the blood stream, and not from embolism of the smaller vessels, where these are present in the endocardial and sub-endocardial tissues attached. In fact, the essential predisposing lesions, in which the circulating bacteria establish themselves, appeared to be small platelet thrombi on the valvular surfaces. Allen and Sirota (1944) concur in finding predisposing lesions, but consider that their essential feature is a degenerative process primarily involving collagenous tissue. On the other hand, McNeal, Spence and Slavkin (1944), in their study of experimental streptococcal endocarditis in the rabbit, report that circulating bacteria are ingested by the endothelial cells of blood vessels all over the body, including those covering the valves of the heart. The valves become infected because, unlike the rest of the vascular endothelium, that on the valves is not bactericidal, and is consequently damaged by the ingested cocci. The injury is then covered by a deposit of fibrin, which, by protecting the ingested streptococci, enables them to set up a local infection.

Okell and Elliott (1935), approaching this problem from a different angle, endeavoured to find a source from which the infecting streptococci might be derived. Before extraction of the teeth, they found streptococci in the blood of 12 of 110 patients suffering from moderate or extensive gum disease, but in none of 68 persons with healthy gums. After extraction, the incidence of positive blood cultures rose, but the bacteræmia observed was transitory, since the blood became sterile, often within ten minutes of becoming infected. Transient bacteræmia of this kind occurred in 72 of 100 patients with gum disease, and in 12 of 38 patients without obvious gum disease. The majority of cocci isolated were of the *Str. viridans* type. These findings have been amply confirmed (for references see Pressman and Bender 1944); transient bacteræmia may follow even light manipulation of infected teeth. The same sequence has been observed after operative manipulation of other infected sites—the cervix uteri (Schottmüller 1911), the urethra (Barrington and Wright 1930), joints, tonsils and prostate (Richards 1932), the organism found depending on the nature of the infection. Tonsillectomy

approaches tooth extraction in the frequency with which it is followed by a *Str. viridans* bacteræmia (see Fischer and Gottdenker 1936, Elliott 1939).

It would seem, therefore, that in any person with oral or tonsillar sepsis, there is likely to be an occasional leak of streptococci into the blood stream, leading to a transitory bacteræmia, this leak being temporarily intensified as the result of operative procedure. These streptococci are, in a normal person, rapidly removed from the blood stream and cause no serious damage to the tissues; but if they come in contact with a congenitally defective heart valve, or a valve already damaged as the result of rheumatic infection, or a valve in which degenerative changes have occurred, they may set up a lasting and slowly fatal infection.

There are recent reports of the cure, by both sulphonamide compounds and penicillin, of this normally fatal disease. Heparin is sometimes given as well, to prevent the deposition of fibrin on the surface of the infected lesions during treatment (see Loewe *et al.* 1944). The data, however, are as yet too scanty to permit any conclusion about the value of chemotherapy. With regard to prophylaxis, attempts have been made to minimize the risk of the bacteræmic showers induced by manipulation of infected lesions in the body. Pressman and Bender (1944), for example, report that sulphanilamide, though it does not reduce the incidence of the transient bacteræmia following tooth extraction, appears to hasten the subsequent sterilization of the blood stream.

CHAPTER 69

ENTERIC INFECTIONS

Among the clinical records left by medical writers from Hippocrates onwards, we have little difficulty in recognizing cases which can, with reasonable certainty, be identified as instances of enteric fever. The separation of this type of infection from the mass of continued fevers was, however, a slow process; and it was only during the first half of the nineteenth century that typhoid or enteric fever finally emerged as a clinical syndrome from among the mass of continued fevers with which it had previously been confused. Various differences in behaviour between typhoid fever and the prevalent typhus, gaol, or famine fever had indeed been noted at much earlier dates. Among these pioneers were Willis (1659) and Huxham (1739); but their descriptions were not sufficiently detailed or complete to carry general conviction. As noted by Creighton (1894), the final recognition of enteric fever in this country resulted from the elaborate analysis of the symptoms of the different types of continued fever carried out by Sir William Jenner between 1849 and 1851. In Germany, the differentiation of typhus from typhoid was clearly recognized by Schoenlein (1839), under the names "Typhus exanthematicus" and "Typhus abdominalis," which have maintained their position in German literature. In France, the observations of Prost (1804), and particularly of Petit and Serres (1813), afforded what was probably the first accurate description of the intestinal lesions; though many earlier records of post-mortem findings are in existence. These observations were confirmed and extended by Bretonneau (1826), Louis (1829), and Chomel (1834)—(see Gay 1918).

The most striking contribution to our knowledge of the natural history of typhoid fever, before the opening of the bacteriological era, is undoubtedly that made by William Budd (1856, 1873) of North Tawton in Devon. Budd had studied under Louis at the La Pitié hospital, and was therefore in a position to identify typhoid fever with considerable confidence. He insisted on its spread by contagion, on the fact that the infective agent was excreted in the fæces, on the rôle played by the contamination of water and milk in the epidemic spread of the disease, and on the possibility that infection might be derived from the excretions of a convalescent patient. His writings afford an admirable example of the value of accurate observations, carried out in the spirit of the field naturalist.

With the description of the typhoid bacillus by Eberth in 1880, and its isolation by Gaffky in 1884, it became possible to attack the problems of enteric infection by the methods devised by the bacteriologist. The subsequent isolation and study of the various species of paratyphoid bacilli showed that enteric fever, though a clinical syndrome, might result from infection with several distinct, though nearly related, bacterial species. For a description of these species reference may

be made to Chapter 30. The studies of recent years have yielded a considerable mass of data with regard to the distribution, in place and time, of the various bacterial types of enteric infection; and this point will be discussed later in this chapter. For the moment we may consider the results obtained in the detailed study of typhoid infection, in man and animals, taking them as representative of the behaviour of enteric infection as a whole, and noting certain exceptions for purposes of comparison or illustration.

Bacteriology.

During an attack of typhoid fever, the causative bacilli can be isolated from the fæces (Pfeiffer 1885), from the urine (Hueppe 1886), from the rose spots of the eruption (Neuhaus 1886), and from the blood (Vilchur 1887). It may be noted that the intensive study of enteric infection in particular samples of the population, to which we shall refer later, has resulted in the demonstration that *Salm. typhi* may occasionally be cultivated from the fæces during the incubation period, or even from the blood of an apparently healthy person, who may soon after develop the disease (Conradi 1907, Mayer 1910). The demonstration of specific agglutinins in the blood, usually attributed to Widal (1896) (since Grünbaum (1896), who noted their appearance earlier, recorded his observations later), has made it possible to study the progress of this particular response to infection, and to correlate the results with those obtained in attempts to isolate the causative organism.

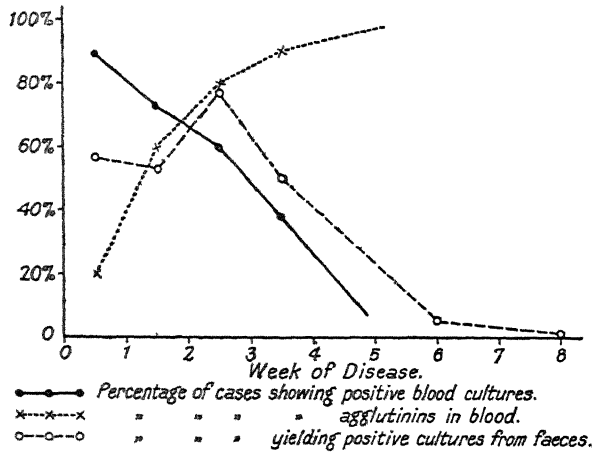

FIG. 283.

A very instructive picture of the usual course of events during an attack of typhoid fever may be obtained by charting, for the successive weeks of the disease, the average frequency with which *Salm. typhi* can be isolated from the blood, or from the fæces, and the frequency with which the serum gives the diagnostic agglutinin reaction. In preparing Fig. 283 along these lines, we have employed for the fæces the figures of Gaehtgens and Brückner (1909), extrapolating by taking values beyond the 4th week intermediate between those recorded by Semple and Greig (1908), and those suggested by the findings of Lentz (1905); for the blood the figures recorded by Coleman and Buxton (1907), again extrapolating beyond the 4th week; and for the agglutinins the figures given by Park and Williams (1925).

As indicated in the figure, the onset of symptoms is associated with a bacteræmia. From the 1st week onwards the frequency with which *Salm. typhi* can be isolated from the blood falls, at first slowly, then more rapidly. By the

end of the 3rd week it can be found in about half the cases; after the 4th week its isolation is infrequent. It must be remembered that we are dealing with a frequency chart, not with the course of events in any individual case. It may be taken that the frequencies noted for the results of blood culture after the 4th week refer to cases which were febrile at that period, since such patients would naturally be selected for investigation. In any given case, it will usually be found that the decline of fever is associated with the disappearance of bacteria from the blood. In cases which terminate fatally as the result of the primary infection, apart from the secondary accidents of hæmorrhage and perforation, the severity of the bacteræmia usually increases until death (Jochmann 1914).

The frequency of *Salm. typhi* in the fæces, on the other hand, increases from the 1st to the 3rd week and then falls somewhat slowly. The frequency curves for blood and fæces cross somewhere about the end of the 2nd week. Before that time, the bacilli are isolated more frequently from the blood than from the fæces; after it, the position is reversed. In attempting deductions from such figures as these, we must remember that differences in technique may have an important influence on our results. There are certain technical difficulties associated with blood culture, and with the isolation of pathogenic bacteria from the fæces; but they are different in kind, and the technical error involved may be quite different in degree. The significant point is the decreasing frequency of detectable bacteræmia, and the increasing frequency of *Salm. typhi* in the intestine, during the first 2 to 3 weeks. This clearly suggests that the main direction of invasion during this period of the infection is from the blood stream to the intestine, not from the intestine to the blood. In the 1st week about 20 per cent. of the cases give a positive agglutination test. The curve then rises sharply, crossing the blood-culture curve just before the end of the 2nd week, and still rising attains a value of 90 per cent. or more by the 4th week; after which it remains at a high level for several weeks.

Data are available which enable us to describe with considerable accuracy the course of the agglutination curve in an individual case of typhoid fever, plotting titre against time. The most extensive records, however—those of Dreyer and his colleagues—refer to results obtained with formolized broth cultures, which react chiefly to the H (flagellar) agglutinins (Dreyer *et al.* 1915, 1916, 1917). We have no such detailed information for the rise and fall of O (somatic) agglutinins; but such evidence as is available suggests that the general form of the curve, at least over the earlier part of its course, is very similar to that followed by the H agglutinins. This question will be discussed more fully in relation to diagnosis. For our immediate purpose we may take it that agglutinins usually appear in the blood between the 3rd and 7th day of disease, rise, first slowly, then more steeply to a maximum between the 16th and 22nd days, and then fall, at first steeply, later (at least in the case of the flagellar agglutinins) very slowly, so that they are detectable for weeks or months after convalescence (Figs. 260, 261, p. 1121).

The rise in agglutinins is usually associated with a decreasing bacteræmia, and the time at which the agglutinin titre reaches its maximum coincides approximately with an amelioration in the patient's general condition, as indicated by a gradual fall in temperature. In this connection the agglutinin curve, so far as it is described in terms of H agglutinins, should be regarded as an indication of a general antibody response, not as deriving its significance from the fluctuation in flagellar agglutinins themselves. There are many reasons for believing that these particular antibodies

have little if any protective value, while the O agglutinins, and apparently the Vi antibody of Felix and Pitt (1934*b*), are of decisive importance from this point of view (see Chapter 47 and later sections of this Chapter).
